FURTHER EXPERIENCES WITH STREPTOMYCIN THERAPY IN UNITED STATES ARMY HOSPITALS

MAJOR EDWIN J. PRASKI AND COLONEL SAMUEL SHELLEY
Medical Corps, UNITED STATES ARMY

EVALUATION of streptomycin was begun in United States Army Hospitals in 1945. This investigation is still in progress. A special research unit established originally at Hulloran General Hospital is now continuing to function at Brooke General Hospital in San Antonio. Here sensitivities of bacteria to streptomycin have been tested and the findings correlated with studies on absorption, distribution, and excretion of the drug in the body following parenteral administration.¹ This unit in addition is carrying on intensive studies on certain types of infections, especially surgical. Data on these and on all patients treated with streptomycin in U. S. Army Hospitals are recorded on special forms for permanent retention. It is our purpose here to present in summary form these cumulative experiences based on an analysis of 1,200 cases.

A complete understanding of the properties of streptomycin is an absolute necessity if the drug is to be used intelligently. The principal characteristics² are as follows: (1) Streptomycin is an organic base freely soluble in water but not in the common organic solvents. (2) Solutions of this compound are remarkably stable both chemically and biologically. Refrigeration is optional for short periods of storage. (3) In contrast to penicillin streptomycin is not destroyed by enzymes or by bacteria. (4) The drug is standardized so that 1 S. unit is approximately equivalent to 1 microgram. (5) A wide variety of pathogenic gram-negative and gram-positive bacteria are susceptible in vitro to streptomycin (Table I). Streptomycin is highly selective in its antibacterial activity, different strains showing marked variation in their sensitivity to the drug, and naturally drug-fast strains are encountered in nearly all species. (6) The activity of the drug is depressed by low pH, dextrose, high concentrations of inorganic salts and reducing substances. (7) Clinical response to this antibiotic is closely related to the in vitro sensitivity of the bacteria. Infections caused by organisms with high in vitro sensitivities may respond favorably, whereas those with low sensitivities are usually refractory to treatment. (8) Absorption, excretion and distribution of streptomycin generally follow the same pattern after parenteral administration as penicillin. The exceptions are that no absorption into the general circulation takes place following administration orally or by nebulization. (9) Bacteria acquire fastness to

monas aeruginosa and *Streptococcus faecalis*. There was no appreciable difference in results of therapy between monobacterial and polybacterial infections provided that all organisms were susceptible in vitro to streptomycin. The marked constitutional signs and symptoms accompanying acute pyelonephritis or acute exacerbations of chronic pyelonephritis responded dramatically to streptomycin, mild urinary tract symptoms and low grade fever responded more irregularly. Patients with paraplegia were benefited by streptomycin therapy, although the effects were rarely permanent except in patients with closed urinary systems and automatic bladders. In these patients clinical remissions were not infrequent in spite of the fact that complete sterility of the urine was not achieved. Presence of obstructive calculi precluded a successful chemotherapeutic result. Advanced renal pathology, undrained abscesses, presence of neoplasms, and infections in the prostate were other causes of failure of streptomycin therapy. Drug fastness is a constant feature in cases in which the prescribed course of therapy has not sterilized the urine. No advantage accrued from the administration of a second course of the drug if the first course had failed to sterilize the urine. Local instillations of streptomycin into the urinary tract via urethral catheters, cystostomy or pyelostomy tubes have been found to be of no value in our experience.⁷

A dosage of 12 to 24 Gm per day of streptomycin in three or four hourly divided doses for three to five days is recommended for treatment of the average infection of the urinary tract due to susceptible organisms. Alkalinization of the urine with streptomycin therapy may be advantageous in selected cases. There is no contraindication to the concurrent use of penicillin or sulfonamides with streptomycin if warranted by the clinical and laboratory findings. The percentage of satisfactory results is highest when the requirements of (1) free flow of urine, (2) susceptible organisms and (3) adequate dosage of the drug are met.

Streptomycin may be a useful agent in uncomplicated nongonococcal urethritis of bacterial origin and in acute epididymitis when the organisms are susceptible.⁸ Uncomplicated gonorrheal urethritis responds to streptomycin as dramatically as to penicillin, except when there is prostatic involvement. In tuboovarian disease, particularly disease of less than one year's duration the antibiotic seems of value in those instances in which penicillin and the sulfonamides no longer are effective. The drug has a place in the management of sinus tracts of urinary tract origin infected with streptomycin sensitive organisms but will not eliminate surgery in most instances. In patients with Reiter's syndrome and amebic cystitis of unknown etiology, no consistently beneficial effects have been observed with streptomycin therapy. Neither parenteral nor oral administration can produce an effective concentration of streptomycin in prostatic secretions, which explains why this compound has not proved beneficial in the treatment of prostatitis.⁹

Typhemia—Ten patients with typhemia were treated with streptomycin, one with the oculoglandular type, one with the typhoidal type, and the others

streptomycin more rapidly than to penicillin (10) This drug is relatively nontoxic when given for short periods of time Toxicity is commonly observed when the courses of therapy are prolonged

Streptomycin is ineffective clinically against anaerobic mycotic protozoan viral and spirochetal infections and worm infestations Rickettsiae of epidemic and murine typhus Rocky Mountain spotted fever and rickettsialpox are sensitive in vitro to streptomycin

*Penicillin-sensitive

RESULTS OF THERAPY

The following are illustrative of types of infections which, in our experience, have shown various degrees of response to streptomycin

Infections of the Urogenital Tract—Four hundred and sixty-five patients with infection of the urinary tract were submitted to critical analysis and study¹² All patients had a complete bacteriologic survey of the urine prior to treatment Culture sensitivity tests revealed that streptomycin had a bacteriostatic effect in vitro on 87 per cent of the bacteria recovered before treatment, while the remaining 13 per cent were naturally drug-fast Seventy-nine per cent of the microorganisms isolated were gram-negative bacilli The remaining 21 per cent were gram-positive cocci, a third of these nonhemolytic streptococci The survey showed that if bacteria are not inhibited in vitro by a concentration of 16 μ g per cubic centimeter, the chances of eliminating them by streptomycin therapy are not good Streptomycin intramuscularly administered can maintain a concentration in excess of 16 μ g per milliliter of blood serum The drug is excreted in very high concentrations in the urine (1,000 μ g per milliliter or more) This suggests that streptomycin acts primarily through delivery by way of the blood stream to the tissues and not through the urine

Of the four hundred and sixty-five patients treated, an outright cure was obtained in 34 per cent of the patients, an additional 21 per cent were improved, that is symptoms were ameliorated, but without complete bacteriologic remission The remaining 45 per cent were not benefited As experience was gained concerning the factors which limit successful streptomycin therapy in urinary tract infections, proper selection of cases led to a progressively higher rate of cures Best results were obtained when infections were caused by *Escherichia coli* Failures were especially frequent when the causal organisms were *Pseudo*

In nearly every instance temperature subsided by a stepladder type of lysis. In most instances the blood was rapidly sterilized of the bacteria, with surgical drainage contributing to the most rapid clearing of the blood stream. Clinical improvement was usually evident by the third or fourth day of treatment. With urinary sepsis the bacteremias cleared rapidly, but pyuria continued until the foci of infection were removed. In cases of bone lesions the infection was localized by streptomycin, but surgical intervention was necessary in the management of the primary focus.

Laboratory studies show that an additive effect is obtained on bacteria from the use of subinhibitory concentrations of streptomycin and penicillin.⁶ Competitive excretions result in slightly higher drug levels when both agents are parenterally administered simultaneously. Streptomycin therapy alone or in combination with penicillin is warranted in the occasional instance of bacteremia due to gram positive cocci where a favorable response to maximal doses of penicillin is not obtained. Streptomycin is indicated also in the therapy of subacute bacterial endocarditis due to penicillin fast nonhemolytic streptococci and gram negative bacilli. Therapy must be continued beyond three weeks, and one must be prepared to accept the risk of labyrinthine disturbances from streptomycin toxicity developing in the occasional patient. On the basis of these experiences, the prerequisites for successful streptomycin therapy of bacteremia are that (1) the organism is sensitive to the drug, (2) acute endocarditis has not yet developed, (3) accessible foci of infection are adequately drained, and (4) the dosage of streptomycin is at least 2 Gm per day, the interval between doses is spread so as to provide bacteriostatic blood levels, and the duration of treatment is long enough.

Infections Involving the Central Nervous System—Streptomycin is now regarded as the drug of choice in the treatment of bacterial meningitis due to susceptible organisms.¹ The results in the U. S. Army series¹³ in general, have been very favorable, especially when treatment was started early in the disease. Of sixteen patients treated, twelve responded favorably and recovered while four died. Deaths were due to (1) use of streptomycin for in vitro resistant *Cryptococcus hominis* infection, (2) advanced sepsis, (3) loculation of pus in the base of the skull in two cases. It is important to remember in the management of the patient with meningitis that streptomycin, like penicillin, diffuses poorly into the cerebrospinal circulation following parenteral administration and that intrathecal injections must be combined with the intramuscular route of administration. The sulfonamides are the only effective bacteriostatic drugs which pass the blood meningeal barrier in effective concentrations. For this reason it may be desirable to combine oral sulfadiazine with streptomycin and/or penicillin therapy.

The scheme of treatment employed in the treatment of meningitis in adults is as follows. When the diagnosis of meningitis due to gram negative bacilli has been established, 50 to 100 mg (average dose, 1 mg per kilogram) of streptomycin dissolved in 10 cc of sterile physiologic saline are administered immediately by the intrathecal route. The injection is repeated every twenty-four hours until the patient has recovered and negative cultures have been

with the ulceroglandular type.⁸ Pneumonia was a complication in three patients, in one of whom it was associated with nephritis. Streptomycin was administered to all patients intramuscularly at intervals of three or four hours in an average daily dose of 2 Gm for periods of seven to fourteen days. Recovery was smooth in all patients, without relapses or complications. The most dramatic responses were obtained in patients with the typhoidal type of infection and with early ulceroglandular tularemia complicated by pneumonia. Infection in suppurating lymph nodes treated by aspiration and followed by one or two instillations of streptomycin subsided rapidly. Healing of open lesions in ulceroglandular tularemia was slow but progressive. The rate seemed related to the duration of the infection. The proposed local injection and topical applications of streptomycin to the ulcerated buboes to provide therapeutic concentrations of drug in relatively avascular tissues remain to be fully evaluated. These experiences support the conclusion of others that streptomycin is the most effective agent now available for the treatment of tularemia.^{1, 5}

Bacteremia—Since 1943 the superiority of penicillin over all other available forms of treatment for bacteremias due to susceptible gram-positive organisms has been clearly demonstrated. Gram-negative bacilli, which are usually resistant to penicillin, also may on occasion invade the blood stream with serious consequences. The mortality rate from gram-negative bacteremias is not as high as in the case of gram-positive coccal bacteremias and the fatalities have been reduced further with the use of the sulfonamides. Streptomycin therapy promises to be even more efficient. The advantages lie in the prompt clinical responses and in the relatively trivial untoward reactions encountered with short courses of therapy.

Thirty-three patients with bacteremia were treated with streptomycin in U S Army Hospitals.¹⁰ In the majority of these the infection arose in the urinary tract, other foci of infection in decreasing order of occurrence were sepsis in the peritoneal cavity, the female genital organs, and bone, including the middle ear and mastoid. Penicillin and/or sulfadiazine failed in twenty of the thirty-three patients before streptomycin therapy was employed. The dosage of streptomycin was between 2 and 4 Gm a day in divided intramuscular doses, and treatment was continued for an average period of fourteen days. Thirty patients recovered and three died. The deaths in each instance were caused by advanced sepsis. Beneficial results were attributed to streptomycin in twenty-six of the thirty patients, and in the four remaining patients the results were of questionable value. In one of these the blood stream was cleared, but sepsis was unrelieved until surgical drainage of an abscess in the kidney was effected. In the second patient with bacteremia also originating in the kidney, blood cultures for *Klebsiella pneumoniae* were again positive after seven days of treatment. There was no response to a second course of the drug, and in all probability the bacteria had become resistant after the first course of therapy. There were no unusual features in the other two cases. One observation is common to the four failures: surgical treatment of the primary focus was not accomplished in conjunction with the chemotherapy.

Six patients with lobar pneumonia in which *A. pneumoniae* were the predominating organism in the sputa were treated with streptomycin. In each instance initial treatment was empirical, with penicillin alone or in combination with sulfadiazine. Each patient remained critically ill in the face of this therapy. After sputum cultures showed *A. pneumoniae* predominating, a change was made to streptomycin therapy. The dosage employed ranged from 0.2 to 0.4 Gm. given intramuscularly every four hours for an average of ten days. Response was striking in all instances, the temperature and pulse having returned to normal limits in seventy-two hours in three instances. There were no relapses. Complete clearing of the lungs, however, varied according to the duration of the infection. Certainly on the basis of this limited experience, streptomycin therapy is indicated in pneumonias caused by the *Klebsiella* organisms. Two cases of persistent *Hemophilus influenzae* infections in penicillin-treated pneumonias showed rapid resolution on streptomycin therapy. A patient with a hemolytic streptococcus pneumonia was developing progressive clinical signs in spite of seventeen days of normally adequate penicillin. The penicillin was discontinued and streptomycin, 0.25 Gm. intramuscularly every three hours, was given with beneficial results. Partial resolution was noted clinically and by x-ray in eight days, and complete resolution two days later. Another patient, who developed postoperatively a type IX pneumococcus pneumonia with bacteremia showed no response whatever to streptomycin. The organism was drug fast. Therapy with a combination of penicillin and sulfadiazine was successful. In two children, no dramatic alteration of the course of the disease attended streptomycin therapy in pertussis with bronchopneumonia. Streptomycin was of no value in the treatment of one patient with atypical pneumonia.

Gram negative bacilli are infrequent primary causes of empyema. They usually are present in mixed culture with the more commonly causal gram positive cocci. The treatment of pure coccal empyema by intrapleural injection of penicillin and by surgery has yielded very satisfactory results. Streptomycin has been tried in only a small series of patients, either alone or in combination with penicillin therapy. The results as a whole are not spectacular. This, in all probability, is due to the fact that streptomycin activity is markedly inhibited in exudates which are acid in reaction. It seems important to emphasize the fact that in all the cases in which improvement occurred the drug was employed in conjunction with adequate surgical drainage. A possible advantage of the combination of streptomycin with penicillin in empyema may be the more effective action of penicillin on gram positive organisms by virtue of the suppressive action of streptomycin on penicillinase producing gram negative bacilli. In two instances of lung abscess and one instance of bronchiectasis a combination of penicillin and streptomycin, administered by nebulization and the intramuscular route, was considered beneficial. Three patients with bronchiectasis were treated only by nebulization and parenteral streptomycin without effect. Two patients with pleuritis, one of undetermined origin and the other secondary to peritoneal suppuration also were treated. There was no beneficial effect in the former patient. Improvement resulted in the latter after the peritonitis was controlled by combined streptomycin and penicillin therapy.

obtained. In addition, 0.5 Gm of streptomycin is administered intramuscularly every four hours. Treatment with sulfadiazine and penicillin may be carried on simultaneously. The total duration of treatment with streptomycin should not exceed seven days.

Streptomycin occupies a place similar to penicillin in the chemotherapy of extradural and solitary brain abscess when caused by susceptible gram-negative or polybacterial infections¹³. The technique of aspiration of pus through a trephine followed by injection of the drug (1 per cent saline solution) through a catheter produces satisfactory results except where bone is involved and sequestrectomy is required. Systemically administered drug should be given simultaneously with the local instillations to protect against dissemination and spread of the infection. It is emphasized that streptomycin does not reach the brain in assayable amounts and that therapeutic levels at the site of the infection can be achieved only by direct injection. Of eight patients with solitary brain abscess with varied bacteriology and primary causes receiving surgical drainage and/or wound revision together with combined systemic and local streptomycin therapy, recovery occurred in seven. The eighth patient died of sepsis.

*Suppurative Infections of the Ear and Mastoid*¹³—Five cases of otitis externa due to susceptible gram-negative bacilli and gram-positive cocci responded favorably with three or four applications daily of cotton packs soaked in 1 per cent sterile aqueous streptomycin solution. Chronic otitis media of mixed bacterial etiology also was treated with topically applied streptomycin, together with parenterally administered drug in a few instances. Of nineteen patients seventeen were benefited, while in two instances of *Ps. aeruginosa* infection no improvement resulted. Combined therapy seems rational because of the possibility of not contacting all reaches of the infection by either route alone. Five to seven days of treatment seem adequate for the majority of cases. Neither local nor systemic toxic phenomena have been observed from topical applications of streptomycin to the ear.

There may be a place for streptomycin alongside penicillin in the surgical and postoperative management of mixed infections of the mastoid. A patient with mastoiditis with lateral sinus thrombosis recovered without sequelae after eventration of the clot with parenteral streptomycin protection.

It is emphasized that streptomycin therapy can be a valuable addition to the therapeutic armamentarium for infections of the ear, meninges, and brain only when the organisms are susceptible to the drug and when sound proved surgical principles are strictly adhered to. There is no contraindication to the concurrent use of penicillin or sulfonamides and streptomycin.

Infections of the Respiratory Tract—Pneumopulmonary infections in which gram-negative bacilli are implicated have been treated with sulfonamides and type-specific antisera with inconstant success. These forms of therapy, therefore, leave much to be desired. Streptomycin has been evaluated in predominantly gram-negative and other types of lesions involving the respiratory tract^{1, 2, 5}.

Two patients treated prophylactically after receiving stab wounds of the abdomen and chest did not become infected

One case each of blastomycosis, actinomycosis caused by *Nocardia asteroides*, and moniliasis was treated with streptomycin. Sustained improvement and remission lasting for an eight months' period of observation were observed in the patient with blastomycosis. The patient with actinomycosis showed remission only while under treatment. The organisms became drug-fast and the disease progressed when therapy was discontinued. No beneficial effect from streptomycin therapy was noted in the patient with moniliasis. Six patients with chronic bronchitis receiving streptomycin and/or penicillin alone or in combination both by the aerosol and intramuscular routes showed elimination of the gram-negative organisms and temporary clinical improvement which was sustained only in those receiving both penicillin and streptomycin. Asthma, Hodgkin's disease, pulmonary sarcoidosis, and other conditions of unknown etiology were not benefited by streptomycin. (Asthma, two patients, pulmonary sarcoidosis, seven, Hodgkin's disease, two, acute pericarditis and rheumatic heart disease, one each)

*Brucellosis*¹¹—Twenty-nine patients with brucellosis have been treated with streptomycin, of whom sixteen had acute and thirteen had chronic cases. Blood cultures were positive for *Brucella* in fourteen of the sixteen patients with acute cases and a bacteremia was present in two with chronic cases. The organisms were very sensitive in vitro to streptomycin. The dosage of streptomycin varied between 1 to 2 and 6 Gm daily (two patients) for an average period of fourteen days. None of the patients with "chronic" brucellosis received any benefits whatsoever from streptomycin therapy. Of those with acute cases, only two of the twelve treated with streptomycin alone had fairly prompt remissions and negative subsequent blood cultures. The bacteremia disappeared in some but not in all of the subjects while the drug was being administered. Exacerbations occurred in five of the twelve patients.

Detailed study of one of the patients under treatment led to the support of the hypothesis that the foci of infection in brucellosis were not penetrated by streptomycin administered parenterally. Oral sulfadiazine, which earlier in the patient's disease was found to be ineffective, was given in addition to the parenteral streptomycin. A prompt response was obtained and the patient has remained well for eighteen months. Five additional patients with acute brucellosis (positive blood cultures for *Brucella* in four) also received combined streptomycin (3 Gm daily) and sulfadiazine (6 Gm daily) for an average period of fourteen days. Two patients are symptom-free at this writing. There were recurrences in two others six and twelve weeks, respectively, after therapy was discontinued. The fifth patient, a 24-year-old woman from whom no *Brucella* were cultured, was unaffected by the combined therapy.

Infections of Intestinal Origin —

*Typhoid Fever*¹² Six patients with typhoid fever were treated. The combined oral and parenteral route was used in three patients, and the parenteral route of administration alone in the other three. No remarkable results were achieved. In only one patient, a 5-year-old child who was given the usual adult

dosage (proportionately three times as great a dose as given the other patients), did the fever end abruptly enough to suggest a response to streptomycin therapy. In two patients who were asymptomatic typhoid carriers, combined oral and parenteral streptomycin therapy did not eliminate typhoid bacilli from the feces. A third carrier, a recent patient with typhoid fever with typhoid peritonitis and positive bile cultures, was benefited by resolution of the bone lesion and elimination of *Escherichia typhi* from all cultures.

Shigella and Salmonella Infections ¹¹ Beneficial effects were noted in ten patients with bacillary dysentery caused by *Shigella sonnei* in four and by *Shigella flexneri* subtypes in six, the majority having been treated previously with sulfonamides. Duration of therapy varied from one to twelve days. The most striking results were obtained in those patients treated during the first attack of illness and in those patients who received a combination of oral and intramuscular streptomycin. The symptomatic improvement was associated with disappearance of the dysentery bacilli from the stools. No relapses were recorded in this series of patients.

Two patients with acute gastroenteritis and blood cultures positive for *Salmonella* organisms were well at the end of seven days' treatment with streptomycin given parenterally and orally.

Oral streptomycin (100 mg per kilogram daily for four to seven days) treatment of three infants with *Salmonella* diarrhea resulted in remission of symptoms and in cultures negative for *Salmonella* for a three week follow up period. Of five patients with recurrent diarrhea showing *Salmonella* organisms, two received oral streptomycin without effect. One of these and three others of this group when treated with combined oral and intramuscular streptomycin obtained symptomatic relief and cultures remained negative for *Salmonella* species. In follow up these patients had mild abdominal cramps and loose stools, but *Salmonella* did not reappear.

Colitis ¹¹ Of the patients with nonspecific ulcerative colitis, nine of those in the acute active phase with systemic manifestations had remissions of symptoms while receiving combined oral and parenteral streptomycin therapy, but the results were not permanent and there was no striking improvement as evidenced by sigmoidoscopic examination. The amelioration of symptoms obtained by streptomycin therapy may be valuable in restoring the patient sufficiently so that surgery can be more safely undertaken. Seven patients in the chronic static phase of colitis showed no improvement whatsoever. In our experience the use of streptomycin is not justified in the medical management of idiopathic ulcerative colitis.

Streptomycin therapy was tested in two patients with amoebic colitis and found to be of no value.

Infantile Diarrhea ¹¹ Thirteen infants suffering from epidemic diarrhea of unknown etiology received oral streptomycin therapy in a dosage of 0.1 Gm per pound per day incorporated in the milk formula. At the start of treatment all were in shock and severely dehydrated. It seemed that streptomycin was the determining factor in saving at least four of the ten survivors. Vigorous fluid and protein replacement were important features of the therapeutic program.

Peritonitis Sixty-three patients have been treated with streptomycin for peritonitis of fecal origin¹⁴ Fifty-eight patients recovered and five died Three of the fatalities were instances of generalized fibrinopurulent peritonitis, and streptomycin was added to the therapy after the patients had become moribund Eighteen of the patients who recovered were treated with streptomycin alone, thirty were treated with streptomycin and penicillin, and ten were treated with streptomycin, penicillin, and sulfadiazine The most striking response was associated with the use of streptomycin in early spreading peritonitis, whether used alone or in combination with the other antibiotic agents Approximately the same course was seen in the resolution of established peritoneal suppuration under streptomycin therapy as under massive doses of penicillin The infections that had already localized showed less consistent response to streptomycin The impression was received that more rapid resolution of these lesions resulted with combined streptomycin and penicillin therapy The most consistently beneficial effects were pursuant to the concurrent intramuscular administration of 0.3 Gm of streptomycin and 100,000 units of penicillin every three hours It seems likely that the complementary antibacterial spectra of these two antibiotics will favor their combined use for peritonitis of polybacterial etiology

Wound Infections—This unit is especially concerned with identifying the indications for, the dosage of, and the adjuvant utility of streptomycin in the treatment of impending and established wound infections At this writing, data on the results of therapy in sixty-one patients with infections of soft tissues have been examined critically Although these data are insufficient to establish precise clinical standards, these cases are sufficiently representative to indicate certain possibilities and limitations of the antibiotic Streptomycin apparently has its chief field of usefulness in the therapy of cellulitis Particularly favorable results were obtained in acute mixed gram-positive and gram-negative infections which were not responding to, or which developed in the face of, penicillin therapy Another use for the drug appears to be the gram-positive cecal infection which has not responded to maximal doses of penicillin within seventy-two hours, or earlier if *in vitro* evidence of penicillin fastness has been secured A third indication for use is the occasional case of streptomycin-sensitive gram-positive cecal infection developing in the patient with idiosyncrasy to penicillin It is worthy of note that the mixed infections in this series occurred predominantly below the level of the diaphragm No strikingly beneficial results have been noted following topical application of streptomycin to wounds It is well to recall that the mere presence of gram-negative organisms in a wound is not per se an indication for streptomycin therapy These bacteria are a feature of necrotic tissue and are eliminated only when all such tissue is removed The only indication for topical streptomycin therapy is in conjunction with débridement The dosage of streptomycin when used alone has been 2 to 3 Gm per day When used in combination with penicillin, the dosage recommended at present is 0.25 Gm together with 50,000 units of penicillin, given intramuscularly every four hours Investigations to establish the optimum dosage of the combination are now being conducted

Two hundred and fifty eight complex wound infections of battle casualties were also evaluated. Almost all of them were associated with chronic osteitis, fibrosis, and diminished local circulation. Usually, a mixed bacterial flora was present. Staphylococci and streptococci were almost constantly identified and clostridia were present in approximately one fourth of the patients. A variety of gram negative bacteria including proteus coli, pseudomonas and aerogenes were associated. Of these patients ninety eight were considered to be benefited and one hundred and sixty were considered as not benefited by streptomycin.

The main task of arresting chronic infection in bone is surgical, not chemotherapeutic. Penicillin and to a lesser degree streptomycin, relieve the surgeon's anxiety about sepsis and protect against spread of infection attending traumatic surgical procedures. Chemotherapy has a definite place in the post operative management of the bone cavity. Bacteria harbored in residual dead tissue and blood clots perpetuate infection unless eradicated. Only local chemotherapy can soak these tissues in high enough concentration. In our experience, combined penicillin and streptomycin therapy is distinctly advantageous in the management of chronic osteitis from the time of sequestrectomy through the time of diverse reconstructive procedures.

Tuberculosis—Streptomycin has now been demonstrated to be a valuable agent in certain forms of tuberculosis. In the pulmonary forms, administration parenterally of streptomycin in daily doses of 20 to 30 Gm. a day for periods up to one hundred and twenty days results in improvement above and beyond that expected from bed rest alone in 50 per cent of the patients. The exudative phase of the infection responds most readily, while fibrotic lesions remain unchanged. Streptomycin in conjunction with collapse therapy enhances the prospects of clinical arrest of the disease in properly selected cases. This antibiotic affords protection against spread of infection postoperatively following thoracoplasty. The results in pharyngitis, laryngitis, and bronchogenic tuberculosis are generally encouraging. Streptomycin has some effect in military tuberculosis and in tuberculous meningitis, though relapse following withdrawal of the drug must be anticipated. Streptomycin in combination with appropriate surgical treatment seems indicated in hematogenous tuberculosis with soft tissue involvement and in bone tuberculosis though observations are still limited.

Streptomycin therapy of tuberculosis is not without danger. There is some relationship between toxicity and dosage and duration of therapy (see Untoward Reactions). Central nervous system effects, especially on the vestibular portion of the eighth cranial nerve, are a common feature of the courses of therapy necessary to affect tuberculous lesions. These effects are slow to reverse themselves and some damage may be permanent.

UNTOWARD REACTIONS

The case records of eleven hundred and fifty three patients in this series were reviewed and the untoward reactions were tabulated. The overall incidence of side effects was 27.9 per cent (three hundred and twenty two patients). In discussing these reactions from the standpoint of incidence, severity, and cause,

it is emphasized that this series was begun in 1945, when streptomycin was relatively impure. As noted by McDermott,⁴ certain untoward reactions are probably the effects of impurities in the streptomycin, while others are caused by the streptomycin molecule itself. It might be pointed out that a number of the side reactions recorded here are now only of historic interest.

Neurologic Disturbances—These are the most important. There are two types, the persistent or slowly regressing, and the transient. Of the transient reactions, encephalomal pallor and tingling of the face and extremities were recorded fifty times. This reaction has appeared as early as following the first intramuscular injection. Disappearance in the face of continued therapy is usual. Flushing of the skin is an occasional concomitant. Tinnitus, which also may appear early, was noted in twenty-eight patients. Vertigo may be either transient or persistent and its appearance should be reason for caution. Neurologic examination is indicated when this symptom appears. Transient vertigo appeared usually between the third and tenth days of treatment and lasted one or more days. It is recorded thirty times, which may be an underestimation of the incidence. Persisting vertigo, which was accompanied by an ataxic gait and absence of vestibular response to caloric tests, was noted in fifty-six patients (5 per cent). All were on courses of therapy ranging from twenty-one to one hundred and twenty days. The incidence was highest in those treated for one hundred twenty days. The earliest appearance of this disturbance recorded is in a patient receiving 3 Gm of streptomycin daily for fourteen days. The incidence in eighty-one patients receiving 0.5 Gm of streptomycin every four hours intramuscularly up to a total of 50 Gm was 3.7 per cent.³ This reaction is slow to reverse itself. Partial deafness was recorded in twelve patients (1 per cent), all were patients with tuberculosis on a one hundred twenty-day program.

Sensitizations—Dermatoses occurred in thirty-five patients. These reactions were accompanied by pruritis and usually by fever and eosinophilia. The manifestations varied from localized macular eruptions over the flexion creases of the forearms or over the sites of injection to generalized rashes. In six patients urticaria presented. The usual appearance of sensitization reactions was between the fifth and tenth days of therapy. Withdrawal of the drug always resulted in subsidence. Reappearance did not always follow a second course of treatment. In some patients the reaction gradually disappeared in the face of continued streptomycin administration in conjunction with antihistamine drug therapy. There were four instances of exfoliative dermatitis, all in patients with tuberculosis. This reaction is serious and requires prompt withdrawal of the drug. Disappearance is gradual.

Urinary Phenomena—Albumin and microscopic examinations were made on a series of forty patients receiving parenteral streptomycin therapy. Slight albuminuria occurred in all instances and cylindruria in twenty-eight. These findings were not present at the conclusion of treatment. Renal irritation in no instance was regarded as sufficiently important to interrupt therapy. Tests for azotemia should be carried out on patients with evidence of prior renal

damage or on patients whose course of therapy is extended beyond two weeks

Histamine like Reactions—These are transient and relatively uncommon with presently used streptomycin. In this series, headache was recorded fifty five times, nausea and vomiting, twenty three times, arthralgia, thirty four times, and asymptomatic fall of 20 mm Hg or more of systolic blood pressure, ten times.

Local Irritations—This complaint, formerly universal, is now less frequently encountered. In our experience, the intramuscular injections of present batches of streptomycin are still followed by some pain and soreness, more so than in the use of penicillin, but we no longer make a practice of diluting the streptomycin in procaine solution. It is our routine to rotate the sites of injection among the deltoids, the hips, and the thighs.

On the basis of this experience, it is concluded that the use of highly purified streptomycin is justified in the treatment of all types of serious infections due to susceptible bacteria. Treatment certainly can be continued with safety for ten days.

SUMMARY

1 Experiences with streptomycin therapy in twelve hundred patients with infections treated in U. S. Army Hospitals have been presented.

2 The wide variation in sensitivity of bacterial species to streptomycin emphasizes the importance of checking the causative organisms in the laboratory for their susceptibility prior to therapy wherever possible. The cardinal principles which govern in the various fields of medicine and surgery must be fulfilled in conjunction with the chemotherapeutic program. Failure of the host to kill small numbers of resistant organisms or the presence initially of many resistant forms, will result in ineffective drug therapy in many instances and in the persistence of drug fast bacteria. Drug fastness to streptomycin is specific and is not carried over to other chemotherapeutic agents.

3 Present indications for the drug include gram negative urinary tract infections, tularemia, bacteremia, pneumonia, and meningitis due to susceptible organisms, and certain otolaryngologic conditions associated with gram negative bacteria.

4 Bacterial pneumonitides caused by streptomycin susceptible organisms are likely to show good responses to streptomycin therapy. Results in bronchiectasis and empyema have not been spectacular.

5 In limited experience, acute brucellosis with bacteremia was favorably influenced when streptomycin was given in combination with sulfadiazine. The drug is of no value in "chronic" brucellosis.

6 Results in typhoid fever have not been encouraging.

7 Streptomycin shows promise in the treatment of bacillary dysentery refractory to sulfonamides and in some types of *Salmonella* infection. It may be influential in bringing about a remission in active idiopathic ulcerative colitis with severe secondary infection caused by susceptible organisms. The drug is not useful against amoebic colitis.

8 Striking results have been obtained with streptomycin therapy in a few patients with early diffuse peritonitis, but the most consistent beneficial

effects were noted when the streptomycin was given in combination with penicillin

9 Streptomycin is complementary to penicillin in the surgical management of wound infections, and may be of value in certain lesions heavily infected with fecal organisms

10 A general statement has been made relative to the preliminary results of streptomycin therapy in tuberculosis

11 The incidence and type of untoward reactions encountered in this series have been presented. It is concluded that the toxicity of presently available streptomycin is sufficiently low to justify its use in serious infections against which it has been shown to be effective

ADDENDUM

Seven patients in all have completed a course of therapy to date, that is, 3 Gm of streptomycin per day together with 6 Gm of sulfadiazine, for an average of twenty one days. The results of therapy are as follows. Two patients are well and symptom free eighteen months following treatment. A third patient has been free of complaints for nine months except for arthralgia of both knee joints and the proximal phalanges of the third and fourth fingers of the right hand. In this patient the agglutination test for *Brucella* organisms was positive once in a dilution of 1:160, but negative when repeated. Opsonophagocytic test was performed by the National Institute of Health and was reported positive in 1:40 strength. This patient has been seen by a number of consultants for joint disorders who feel that the arthritic process is rheumatoid rather than due to brucellosis. In two other patients relapses occurred on the seventh and twelfth weeks after treatment. A second course was not given because both patients suffered moderately severe vestibular disturbances. A sixth patient is well at this writing, but the period of observation has been for a duration of only three months. A seventh patient, in whom positive blood cultures were never obtained, was uninfluenced by the combined therapy.

SEROLOGIC STUDIES OF INFLUENZA MADE IN BOSTON DURING THE WINTER OF 1945-1946

MAXWELL FINLAND, M.D., MILDRED W. BARNES, M.S., MANSON MEADS, M.D.,
AND EDWIN M. ORY, M.D.
BOSTON, MASS.

THE 1945 epidemic of influenza B which was recognized in many parts of this country and in other countries¹⁻³ reached its peak of incidence in and around Boston during the latter half of December, 1945. This epidemic offered an opportunity to make some serologic observations during and after an outbreak of influenza B similar to those that were made in this laboratory during and after the outbreak of influenza A that occurred here in December, 1943.⁴ The reactions of the viruses obtained during the height of the 1943 epidemic and the antibody response to characteristic infections occurring at that time indicated that the epidemic cases were caused chiefly by strains of influenza A virus similar to PR8. The postepidemic cases of clinical influenza on the other hand, were atypical not only with respect to the viruses which were isolated from some of them but also with respect to their antibody responses to both their own strains and to the standard PR8 strain. There was no evidence of infection with influenza B in any of the cases studied.

After the influenza A epidemic it was also found that the sera of most persons giving a characteristic history of influenza during the period of the epidemic had significantly elevated titers of antibodies to PR8 demonstrable for as long as twelve weeks after the onset of these symptoms. Such elevated titers could not be found during the same period in the sera of persons who denied having had any symptoms of acute respiratory infections or who had had symptoms which could be distinguished readily as those of the common cold and not influenza.

Of particular interest were the high titers of antibodies to PR8 that were demonstrated in severe cases of bacterial pneumonia which occurred during and shortly after the epidemic and in which there was an antecedent history of clinical influenza. Those findings and the isolation of influenza virus from the lungs of three patients with fatal cases suggested that the occurrence and severity of the pneumonia in such cases were related to the influenza virus infection.

The present paper deals chiefly with the results of serologic tests for influenza antibodies in cases of clinical influenza and other acute respiratory infections which occurred during and for a few weeks after the epidemic prevalence of influenza B. The results of tests made on two other groups of sera are also included. One group consisted of paired sera obtained during and shortly after

the height of the epidemic from persons who were entirely free of illness, and the other consisted of single samples from a somewhat larger group of persons obtained a few weeks after the epidemic had subsided. The results of attempts at isolation and identification of virus from patients with acute cases in this epidemic and the serologic findings in cases of pneumonia are left for separate consideration elsewhere¹⁻¹⁶

MATERIALS AND METHODS

Serologic Tests—Both inhibition of chicken cell agglutination and complement fixation tests were carried out in this study. The antigens employed included the PR8 strain* of influenza A and the Lee strain* of influenza B and two strains, WC and MF, of influenza B isolated from patients early in the course of this study. The details of the collection and preservation of the sera, the serologic methods, and the manner of reading and recording the end points were identical with those used in a collateral study¹²

Cases Studied—Included in the present studies were members of the hospital and laboratory staff, both with and without illness, and patients admitted to the regular adult medical wards of the hospital between the middle of December, 1945, and early in March, 1946. Control sera obtained early in the study were available from some of the hospital and laboratory personnel who subsequently developed respiratory infections. With a few exceptions (noted in Table III) patients admitted to the hospital with clinical and x-ray findings of pneumonia are omitted here, since they are considered separately elsewhere¹⁶

Clinical Findings—The clinical features of the cases of influenza were quite characteristic and were similar to those observed in the Needham outbreak¹². In the patients who were seen during the acute illness, an attempt was made to evaluate and classify the clinical findings at that time. This was done again in all of the patients when all of the clinical findings were available and entirely without reference to the serologic data. Those with findings that fit the characteristic picture of the epidemic disease, namely chills or chilly sensations, fever, prostration, headache, eyeball soreness, generalized aches, mild sore throat, and some cough, were classified as having clinical influenza and the severity of their illness was graded 1 plus, 2 plus, or 3 plus. Patients with a minimum of fever and systemic symptoms but with moderate or marked coryza, with or without cough, were classified for convenience as having "colds". A third type of illness was also recognized in which the systemic symptoms resembled somewhat those of influenza but the patient suffered chiefly from anorexia, nausea, vomiting, and diarrhea and had no symptoms referable to the respiratory tract—so-called "intestinal flu."

RESULTS

The cases studied have been arranged for convenience into two main groups, one including patients with acute respiratory infections and the other those without such infections. The former was further arranged into four subgroups to include patients in whom there was serologic evidence of infection with

*Originally obtained from Dr. Thomas Francis, Jr., Ann Arbor, Mich.

influenza B, patients in whom studies of acute and convalescent phase sera failed to yield evidence of infection with either influenza A or B patients with severe acute respiratory infection, including five who had fatal cases from whom sera were available only during the acute phase of the illness and finally those in whom there was serologic evidence of infection with influenza A. The group without respiratory illness was composed of two subgroups a small number of hospital and laboratory workers from whom control sera were obtained in the second week of December and again about three weeks later and in whom no respiratory illness developed during the course of this study and hospital personnel and ward patients who were under treatment at the time for nonfebrile illness other than acute respiratory infections and who each contributed a single specimen of serum toward the end of this study. The results of the serologic findings in each of these groups of cases will be considered separately. They will then be summarized in order to bring the findings in the various groups into proper perspective.

PATIENTS WITH ACUTE RESPIRATORY INFECTIONS —

Group I Patients With Serologic Evidence of Influenza B Infection — The relevant findings in twenty three such patients are listed in Table I. In each of these patients there was at least a fourfold rise in titer of the influenza B antibodies and much greater rises were noted in almost every instance. For the most part rises of similar grade were demonstrated by both the agglutinin inhibition and the complement fixation tests with the Lee strain and with the two epidemic strains. There were very few discrepancies, as for example in Patients 4, 7 and 9 in whom the agglutinin inhibition test with one or another of the B viruses showed little or no rise while significant rises were noted by complement fixation with the same virus or, indeed, by the same test with another of the B strains.

There was no appreciable rise in titer of PR8 antibodies demonstrable by either of the tests used in any of these cases. The initial titers of these antibodies were low except for a few elevated titers of agglutinin inhibition.

Each of these patients with the exception of the first one, had an infection which was considered to be characteristic of the epidemic influenza and which began between Dec. 12 and Jan. 3. The illness however varied considerably in these cases both with respect to the height and duration of the fever and the severity of the systemic symptoms. Leucocyte counts were done during the acute illness in most of these cases. Only two patients showed elevated counts 11,700 in one and 14,000 in the other and both of these patients had moderately severe tracheobronchitis without physical or x-ray signs of pulmonary infiltration. The leucocyte counts in slightly more than half of the remaining cases ranged between 4,200 and 6,500 and in the others they ranged between 7,000 and 10,000.

The only patient without the characteristic findings of clinical influenza (Patient 1) had a mild convulsion which began Dec. 6 lasted for ten days and was not accompanied by fever or systemic symptoms. In this case a rise in the B antibodies occurred from low titers after the eighth day. In five additional

Only two sera are listed in each case. Intermediate and later sera were obtained and studied in almost every case but these are omitted from this table and from Tables II and III. Those selected for inclusion in these tables showed the maximum changes observed.

Symptoms considered typical of influenza are graded according to severity as + ++ or +++ C coryza and/or cough without systemic symptoms D gastrointestinal symptoms pre dominant.

*Relapse with increase in severity

†Homologous virus

patients there was another distinct illness preceding the one considered to be influenza. This antecedent illness was classified as a common cold in four instances and as "intestinal flu" in the fifth. The interval between the onset of the two illnesses was three days in one patient and from eight to thirty one days in the others, and the initial serum was obtained up to three days after the onset of the second illness. In none of these cases, however, was a significantly elevated titer of antibodies for either the A or B viruses demonstrated in the acute phase serum to suggest a possible earlier influenzal infection. Patient 11 may be an exception since an elevated titer of agglutinin inhibition was demonstrated in the first blood with the PR8 strain. The corresponding complement fixation titer, however, was not correspondingly elevated in that serum and the interpretation of this finding must remain in doubt. Patient 6 was admitted on the eleventh day after the onset of what was considered to be a typical but mild influenza from which he seemed to improve until a relapse occurred with similar but somewhat more severe symptoms three days prior to entry. The Lee antibodies were elevated in the initial blood obtained on entry but later showed a significant rise suggesting that the initial infection was indeed influenza B.

Group II Patients Without Evidence of Influenza A or B Infection—For reasons which will become apparent later, the patients in whom tests of acute and convalescent sera failed to disclose any evidence of infection with either influenza A or B were divided into two groups according to the date of onset of their illness. Those in whom the illness began before the second week in January corresponding to the dates of onset in the cases just described, will be considered first. The few patients whose illness began after the middle of January will then be discussed.

A Patients With Onset of Illness Prior to Mid-January Whose Sera Failed to Show an Antibody Rise There were twenty one such patients and the findings are shown in the first part of Table II (Patients 24 to 44). There was no antibody rise whatever in any of these cases to PR8, Lee B or either of the epidemic strains demonstrable by either of the tests used. The initial titers in these cases were low, for the most part and corresponded to those observed in the patients in whom rises in influenza B antibodies were demonstrated.

The illness in thirteen of these twenty one patients was similar in most respects to that observed in the previous group and was classified as influenza of varying severity. In the other eight patients the illness clinically either resembled the common cold (four cases) or the symptoms were predominantly gastrointestinal (two cases) or both of these types of illness occurred in succession (two cases).

B Patients Whose Illness Began After Mid-January and Whose Sera Failed to Show an Antibody Rise There were only eight patients in this group and the findings are shown in the lower part of Table II (Patients 45 to 52). In this small group there seemed to be a higher proportion of sera in which agglutinin inhibiting antibodies for PR8 were in the high range. The titers otherwise were similar to those observed prior to Jan 7. Each of the patients

Symptoms considered typical of influenza are graded according to severity as + ++ or +++ C cough and/or croup without systemic symptoms D gastrointestinal symptoms pre dominant

had an illness which was characteristic of the epidemic influenza. One had a second illness classified as a cold which began one day prior to the time the initial blood was taken.

Group III Findings in Acute Phase Sera—There was a group of twenty patients with severe acute respiratory infections from whom sera were obtained during the acute phase of the illness, but later specimens were not available. Almost all of them had symptoms that began before mid January and were classified as those of influenza. In some of them these symptoms were followed by the typical findings of pneumococcal pneumonia. There were five deaths in this group but autopsies were not obtained in any of them. Agglutinin inhibition titers greater than 64 against PR8 were noted in two patients and against Lee in one patient, but the corresponding complement fixation titers were low in each instance. The remaining titers of antibodies to the PR8 and Lee strains in this group of cases were all low and corresponded to those found in the acute phase sera in those patients who later showed a rise against the B strains.

Group IV Patients With Serologic Evidence of Influenza A Infection—There were thirteen patients in whom the serologic findings indicated infection with influenza A. The relevant data in these cases are summarized in Table III. The onset of illness in all of these cases occurred between Jan 18 and Feb 3, except in Patient 53 whose symptoms began Dec 28. In five of these patients (Patients 56, 57, 62, 63, and 64) the initial serum obtained between the seventh and twenty-first day after the onset already had significantly elevated PR8 antibody titers. However, in contrast to the isolated instances of elevated titers of agglutinin inhibition by PR8 noted in the previous groups of cases in which there was no corresponding elevation in the titer of complement fixing antibodies obtained with the same virus, the elevated titers in the present five patients were demonstrated by both tests. In the remaining eight patients, significant and usually marked rises in antibodies occurred to the PR8 but not to the Lee virus.

Several attempts to isolate a virus from pharyngeal washings obtained during the first day of illness in two of the patients (Patients 54 and 60) were entirely unsuccessful.

There were two patients in this group in whom there was definite serologic evidence of successive infections, first with influenza B and then with influenza A. One of these Patient 58, was originally admitted to the hospital for influenza which began Nov 30 and was accompanied by characteristic symptoms and physical and x-ray findings of atypical pneumonia. The patient recovered fully and later was readmitted because of a second attack of influenza the symptoms of which began Jan 27. The titer of antibodies for the Lee strain had risen from 20 to 640 by agglutinin inhibition and from 3 to 1,792 by complement fixation during the first illness. These titers had already dropped appreciably at the time of the second hospital admission. There had been no rise in PR8 antibodies during the first attack.

The early symptoms in the original attack of influenza in the second patient Patient 59 were quite characteristic of the epidemic disease and began on Dec 24. These were followed by a typical course of type 5 pneumococcal pneumonia which began abruptly on Dec 29. During this illness there was a marked rise

*Bronchopneumonia onset 2/12 W B C 11900 etiology?

†Had influenza with atypical pneumonia (onset 11/30) with rise in influenza B antibodies from 20 to 640 by agglutinin inhibition test and from 3 to 1792 by complement fixation test. Cold agglutinins could not be demonstrated in any of the sera

‡Influenza (onset 12/24) and type 5 pneumococcal bronchopneumonia (onset 12/29) with marked rise in influenza B antibodies (from titer of 4 in acute phase) No definite symptoms associated with influenza A infection

§Type 5 pneumococcal bronchopneumonia onset 2/6 W B C 6600

||Type 4 pneumococcal lobar pneumonia onset 2/2, W B C 3000

in antibodies to PRS but not to the Lee strain although the initial titers to both of these viruses were low. The patient was discharged from the hospital and subsequent specimens of serum were obtained when the patient returned on two occasions for checkup examinations. The sharp rise in PRS antibodies that occurred following this patient's discharge was not associated with any subjective or objective evidence of infection.

In all but one of the remaining patients the infections which occasioned the rise in influenza A antibodies could not be distinguished clinically from those which were associated with the rises in influenza B antibodies. In Patient 53 the illness was characterized by coryza, slight sore throat, and slight productive cough without fever or systemic symptoms, the leucocyte count was 8,700

laboratory workers from whom sera were obtained during the end of the second week in December and again during or after the first week in January. They had no symptoms of any illness during this interval or in the preceding few weeks. None of these individuals showed any rise in titer of antibodies for either the PR8 or the Lee virus. Low titers were obtained in all of these sera except for agglutinin inhibition titers greater than 64 obtained in both sera from one of this group with the Lee strain without correspondingly elevated complement fixation titers.

Group VI Influenza Antibodies in Sera Obtained After the Epidemic—In order to obtain some idea as to whether a retrospective history of respiratory infection during the epidemic might be reflected frequently in a high influenza antibody titer a few weeks later, single specimens of sera were obtained between Feb 16 and 23, 1946, from sixty-two individuals not included in any of the previous groups. Most of them were from young adult patients hospitalized for illnesses other than acute respiratory infections and others were from members of the hospital staff. Each person was questioned in detail concerning any illness that occurred during the preceding three months. All respiratory illnesses were then classified according to whether they most resembled colds or clinical influenza and whether they occurred before or after the middle of January. The occurrence of such infections as determined in this manner and the results of the tests for influenza antibody in their sera are listed in Table IV.

The outstanding finding in this group is the comparatively large proportion of sera showing elevated titers (greater than 64) of agglutinin inhibition of the PR8 strain without corresponding elevation of the complement fixation titers with the same strain. There were a few instances of elevated titers of agglutinin

inhibition of the Lee strain and in some of these sera the corresponding complement fixation titers were also higher than average. When this group is subdivided according to the recent history of respiratory infections, the numbers in each category are too small to permit any significant comparisons. However, except for the somewhat greater frequency of high agglutinin inhibition titers with both the PR8 and Lee strains in the person giving a recent history of clinical influenza, there seemed to be no striking predominance of significantly elevated titers in any group.

There were three persons in this group (Patients 81, 113, and 115) who had received an immunizing injection of influenza A and B vaccine in November 1945. One of them showed elevated titers by both tests against all the four strains of virus used. The other two showed elevated agglutinin inhibition titers with the PR8 and Lee strains without correspondingly elevated complement fixation titers. One of the latter also gave a history of clinical influenza during the height of prevalence of influenza B.

Summary of the Serologic Findings—The distribution of titers of PR8 and Lee antibodies in the seven groups that have been discussed is shown in Table V. The average titers for each of these groups are also shown. Groups I and IV* stand out clearly from among the others. In Group I there was a similar distribution of titers in the lower range of both agglutinin inhibition and complement fixation of the PR8 strain in both acute and convalescent phase sera, whereas there was a shift in Lee antibodies from low titers in the acute phase to titers in the higher range in the convalescent phase sera. In accord with this distribution the average titers were essentially the same for acute and convalescent sera in the tests done with PR8 (though the actual numbers were higher for the average agglutinin inhibition titers than for the complement fixation titers), while the average anti Lee titers were about twenty fold greater during convalescence in the agglutinin inhibition tests and about thirty five fold greater in the complement fixation tests.

The reverse was true in Group IV. The number of cases in this group was small but the distribution of anti Lee antibodies was in the low range and the average titers were low and were the same by both tests in the acute and convalescent phase sera. The tests with PR8 on the other hand gave low titers in the acute sera and high titers during convalescence. The average anti PR8 titers were about ten times greater in the convalescent phase sera than in the acute phase sera done with either test.

In Groups IIA, III, and V the distribution of titers and the average titers were all similar to those found in the acute phase sera in Groups I and IV. In Groups IIA and V this was true for both the early and the late sera.

Groups IIB and VI are similar in several respects and stand out from the other groups. The sera in both of these groups were obtained after the date of the last proved case of influenza B. In each instance there was a smaller proportion of very low titers and more of the intermediate and the moderately elevated titers of agglutinin inhibition with PR8. The averages of these titers

*The group designation corresponds to the one used in Table A and also to the one used in the previous section heading in the text.

§ Corrected average (after excluding sera obtained on or after the seventh day or those indicated by †) shown in parentheses

|| Acute blood on seventh day

†† Earlier influenza B infection the values in the e two cases are excluded in the corrected averages

were two to three times greater than in all groups except Group IV (convalescent sera from the patients with influenza A). The values for the convalescent phase sera in Group IIB were slightly but not significantly higher than for the acute phase sera. On the other hand, the distribution of the complement fixation titers was the same and the average of these titers obtained with the same virus in these two groups of cases was not elevated and corresponded to those observed in all other groups except in the convalescent phase sera in Group IV.

With respect to influenza B antibody, however, Groups IIB and VI differed. In the former, the distribution of titers was in the low range and the average titers in both the acute and convalescent phases were low and corresponded to those observed in Groups IIA, III, and V and in the acute phase sera in Group I. In Group VI, on the other hand, there was a greater proportion of intermediate and slightly elevated titers of Lee antibodies and the averages of these titers were two to three times those found in the remaining groups other than Group I (convalescent sera from patients with influenza B). In these respects the findings with the agglutinin inhibition and complement fixation tests were similar.

Comparison of Results Obtained With the Lee Strain and With Two Epidemic Strains—It will be seen from Tables I, II, and IV that, although there were some discrepancies in individual sera, the results obtained with the standard Lee strain and with WC and MF (the two strains of influenza B virus that were isolated early in the course of the epidemic) were very similar. The average titers of all the sera of these three groups that were tested with the three strains are shown in Table VI. Considering the rather small numbers involved, the average titers obtained in each group with the three strains were remarkably similar.

COMMENT

The serologic findings in Groups I and IV indicate quite clearly that both influenza B and influenza A occurred in Boston during the winter of 1945-1946. The dates of onset of illness in the patients of those two groups indicate that, for the most part, there were distinct and consecutive outbreaks. In this study

the proved cases of influenza B with one exception, had an onset between Dec 12 and Jan 3, the onset in the cases of serologically proved influenza A, again with one exception occurred between Jan 18 and Feb 3. Viruses giving characteristic reactions of influenza B were isolated from patients with acute cases during the former period,¹ but attempts to isolate viruses from two others with acute cases of influenza A were not successful.

The occurrence of both influenza B and A with a predominance of the former, was also reported in the corresponding epidemics in Australia⁴ and Great Britain.^{5, 6} In these countries too, there appeared to be consecutive outbreaks although there was somewhat more overlapping. Strains of both types of virus were isolated in Australia. Among the Australian cases there were two and possibly three instances of consecutive infections with influenza B and A in the same individuals, and two such cases are included among those reported here. Evidence was also obtained from complement fixation tests done on serum pools that influenza A occurred sometime after the influenza outbreak of December 1945, in New York State.¹³ The isolation of influenza A virus in the Chicago area in December, 1945,¹⁷ and serologic evidence that influenza A alone occurred in an outbreak at a boys' school thirty miles from Boston between Jan 9 and Feb 6¹⁸ have also been recorded.

Symptomless infection associated with a significant rise in influenza virus antibodies was observed during this study in only one instance namely the influenza A infection that occurred in Patient 59 (Table III) following the attack of clinical influenza which had given rise to influenza B antibodies. Not enough observations were made to determine the incidence of such symptomless infections, but the findings in Group VI suggest that they were not infrequent with the B virus and those in Groups IIB and VI suggest that they may also have occurred with some type of A virus.

As for the remaining serologically proved cases of influenza B (Table I) and A (Table IV), the rise in antibodies followed a characteristic attack of clinical influenza in every instance except in one patient of each of these groups. A similar observation was made in the Australian cases.⁴ The symptomatology varied in the cases that were not associated with an antibody rise both in those which occurred during the prevalence of influenza B and in those which occurred later when cases of influenza A were encountered. Some of those patients had symptoms of clinical influenza indistinguishable from those experienced by the patients showing definite antibody rises but a large proportion of them had symptoms that were more like those of the common cold or were predominantly gastrointestinal. Furthermore, in the patients who had two distinct infections one resembling clinical influenza and the other more like the common cold the antibody response seemed to be temporally related to the former.

The failure of certain patients with typical symptoms of influenza to show antibody rises to the epidemic strain even when they have low titers during the acute phase has been noted frequently by others. This has been observed even in patients with typical illness from whom a virus has been isolated¹⁴ or who had been infected experimentally.¹⁹

The elevated titers of agglutinin inhibition of PR8 not accompanied by correspondingly elevated complement fixation titers are of some interest. They occurred in sera obtained after the middle of January from patients with clinical influenza who failed to show any significant antibody rise with the viruses used (Group IIB) and were also noted in the sera obtained from individuals picked at random late in February (Group VI). These may represent, in part, a response to infection with an influenza virus related to but not identical with PR8. Such a possibility is not inconsistent with the occurrence of typical rises of PR8 antibodies demonstrable by both agglutinin inhibition and complement fixation in other individuals, as noted in Table III.

The findings in Group VI suggest, in addition, that an appreciable proportion of the individuals in that group had had recent infection with influenza B, as evidenced by the elevated titers to those viruses demonstrable by both tests. The correlation of the elevated titers with the occurrence, time, and character of the infection as noted in the histories of these individuals was not very good. Some evidence was previously adduced to suggest that the WC and MF viruses were antigenically different from the Lee strain.¹²⁻¹⁵ Although similar antibody responses to all three strains were observed in most patients, there were sera which showed definite discrepancies both in the present cases and in those reported from Needham.¹⁴ Further observations¹⁶ have since been made to support the view that WC and MF are more closely related antigenically to the Australian strain BON,²⁰ and similar strains have been identified both in Australia²¹ and Great Britain during the 1945 epidemics in those countries.

SUMMARY AND CONCLUSIONS

Both influenza B and influenza A were prevalent in Boston during the winter of 1945-1946. Influenza B was responsible for the major outbreak that occurred in December, 1945, and no acute cases proved to be due to this virus were encountered after the first week in January. Cases of serologically proved influenza A were encountered almost entirely after the middle of January. Two cases were observed in which there was definite serologic evidence of consecutive infections first with influenza B and a few weeks later with influenza A. There was also some evidence of symptomless infections with viruses of both types.

Almost all of the patients in whose sera a rise in specific antibodies to one or another of the influenza viruses was demonstrated had respiratory and systemic symptoms which were characteristic of clinical influenza. Similar symptoms were noted during the same period in other individuals whose sera failed to show such a rise. A large proportion of the patients who failed to show a rise in influenzal antibodies, however, had an illness which was more like the common cold or had predominantly gastrointestinal symptoms.

INFLUENZA AND PNEUMONIA

SEROLOGIC STUDIES DURING AND AFTER AN OUTBREAK OF INFLUENZA B

MAXWELL FINLAND, M D, EDWIN M ORY, M D, MANSON MEADS, M D
AND MILDRED W BARNES, M S
BOSTON, MASS

IT IS generally assumed that deaths from influenza are usually associated with pneumonia, as seemed evident from clinical and pathological findings during the pandemic of 1918. Excess mortality rates during periods of epidemic prevalence of influenza, however, are credited as much to increases in deaths from other causes as they are to increases in deaths from influenza and pneumonia.¹ Evidence for a direct relation of influenza virus infection to the occurrence or severity of pneumonia in individual patients is rather scant.

This relationship of influenza virus infection to bacterial and other pneumonias has been a matter of interest in this laboratory for the past few years. Some serologic evidence for an association of influenza A infection with cases of pneumococcal and, particularly, of staphylococcal pneumonia was obtained during the 1940-1941 outbreak.²⁻⁴ Presumptive evidence for the presence of influenza A in the lung of a patient with a fulminating case of staphylococcal pneumonia was obtained at that time.²⁻⁴ Significantly elevated titers of influenza A antibodies also were demonstrated in cases of pneumonia of varied etiology which followed attacks of clinical influenza during the epidemic of 1943-1944.⁵ In addition, influenza A virus was isolated from the lungs of five patients with fatal cases.⁶ Two of the strains were from patients with the fulminating acute hemorrhagic and edematous type of staphylococcal pneumonia, a third was from a patient with lobar pneumonia in whom type 1 pneumococcus was obtained from the sputum, blood, and lungs, and cultures from the two remaining patients yielded no significant pathogenic bacteria and only a few alpha hemolytic streptococci from sputum and lungs. The onset of pneumonia occurred from one to three days after the onset of symptoms of clinical influenza in these five patients.

Other workers also have reported the isolation of influenza A virus from the lungs in acutely fatal cases of staphylococcal pneumonia, three such cases were reported from the 1936-1937 epidemic in England,⁷ and one occurred in Philadelphia in January, 1939.⁸ Various other types of lung changes were observed in patients with clinical influenza in the 1936-37 epidemic,^{7,9} but the commonest lung lesion in proved cases of influenza A infection in that outbreak was considered to be a "bronchiolitis".⁹

The occurrence of pneumonia during epidemics of influenza B also has been reported, but in these outbreaks the evidence for the association of the virus with the individual cases of pneumonia is scant. Four fatal cases of pneu-

Miss Mary J. Graham rendered technical assistance during part of this study.
Received for publication Oct. 30, 1947.

pneumococcal lobar pneumonia and four other patients with pulmonary involvement were observed during an epidemic of influenza B in a mental institution in Minnesota.¹⁰ The presence of influenza B infection during an epidemic of type 1 pneumococcal pneumonia in Northville, N. Y., was demonstrated serologically.¹¹ In neither of these two outbreaks, however, was the relation of the influenza B virus infection established in any of the instances of pneumonia either serologically or by demonstration of the virus. Only one case has been reported prior to the epidemic of 1945 in which influenza B virus was isolated from the lung of a patient with a fatal case.¹ In this case as in most of those previously mentioned in which influenza A virus was yielded from the lungs there was a fulminating acute hemorrhagic and edematous type of *Staphylococcus aureus* pneumonia.

During a localized outbreak of influenza B which occurred in the Bahamas in 1945,²³ lobar pneumonia was recognized as a complication occurring from 0 to 14 days after the onset of clinical influenza in about 10 per cent of the cases. The relation of the virus was not established in any of the cases of pneumonia in this outbreak. Influenza B virus was isolated in Melbourne during the 1945 outbreak²⁴ from bronchial secretion obtained at autopsy from a patient with an acutely fatal case of staphylococcal pneumonia which began five days after the onset of influenza. This virus was also isolated in January, 1945, from throat gargling obtained "from a nurse in Surrey with a severe form of influenzal pneumonia."²¹

The epidemic of influenza that occurred in Boston in December, 1945, offered an opportunity to make some serologic studies of influenza antibodies in cases of pneumonia that occurred during and shortly after the time when influenza B, and later influenza A infections were demonstrated in cases of clinical influenza.¹⁶ The findings in these cases are reported here.

MATERIALS AND METHODS

Choice of Patients—All of the patients chosen for this study were admitted to the Medical Wards of the Boston City Hospital mostly during December, 1945, and January, 1946. Detailed histories were obtained with respect to the pneumonia and to any antecedent acute respiratory illness in an attempt to determine the time of onset of these infections as nearly as possible.

Bacteriologic studies of blood and sputum were carried out during the acute illness in almost all of the cases. Blood for serologic tests was obtained during the acute febrile stage of the illness and again at intervals thereafter. Patients from whom samples of serum were available within the first week of the onset of respiratory illness but not later are excluded here. The findings in the sera of several such patients, including five with fatal cases, are given elsewhere.¹⁶ No attempts were made to isolate viruses from these patients and autopsies were not obtained in any of the fatal cases.

Clinical Findings—The onset of pneumonia during or after a simple upper respiratory tract infection was usually marked by one or more of a number of manifestations: (1) the sudden occurrence of a brisk chill or of pleuritic pain

or both, (2) a recurrence of chills or chilly sensation, (3) the appearance of bloody or rusty sputum, (3) dyspnea, and (4) a change in the character and severity of the cough. The criteria for the classification of the upper respiratory tract infections were the same as those used in collateral studies of this outbreak reported elsewhere¹⁶⁻¹⁷. The pneumonias were classified as either lobar or atypical (broncho-) pneumonia according to the clinical and x-ray findings. Some of the latter resembled characteristic cases of primary atypical ("viral") pneumonia.

Serologic Tests—The viruses used were the PR8 strain of influenza A and the Lee strain of influenza B* and two strains WC and MF of influenza B isolated from uncomplicated cases of clinical influenza early in the course of this outbreak. The inhibition of chicken cell agglutination and the complement fixation tests were both carried out in every instance. The details of the methods used and the manner of recording the titers are the same as those used in other parallel studies¹⁷.

Tests for cold agglutinins were also carried out in all of these sera by the method usually employed in this laboratory¹⁸. The lowest final dilution of serum used in these tests was 1:10.

RESULTS

A total of sixty-nine patients was available for study. They have been divided for convenience into three groups: those in whom a significant rise in influenza B antibodies was demonstrated, those whose initial serum showed significantly elevated titers of influenza B antibodies, and those in whom the serologic findings failed to reveal any evidence of recent influenza virus infection. The findings in each of these groups will be considered separately.

Group I: Patients Whose Sera Showed a Significant Rise in Titer of Influenza B Antibodies—There were eleven such patients, seven were women and four men and they ranged in age from 13 to 69 years. The relevant findings pertaining to the influenza and the pneumonia and the results of the serologic tests in these patients (1 to 11) are shown in the upper part of Table I. There was an illness which, from the history was considered to be clinical influenza in all but one of these cases. The first symptom of this illness began on November 30 in one patient and between December 18 and January 11 in the others. The onset of the pneumonia occurred on the same day in three cases, and one to ten days later in the others. In Patients 6 and 11 there were symptoms suggesting, respectively, an exacerbation of the original attack after five days and a second attack after six weeks.

The findings in the lungs were those of typical lobar pneumonia in two of these patients and cultures of the sputum yielded predominantly pneumococci in both. In all the others there was patchy consolidation. In Patient 1, the findings in the lungs closely resembled those of primary atypical pneumonia, sputum cultures yielded only alpha hemolytic streptococci. *Staph aureus* was the predominant organism in repeated cultures in four other patients and pneumococci predominated in the remaining four, with staphylococci being recovered in moderate

*Both originally obtained from Dr. Thomas Francis, Jr., Ann Arbor, Mich.

numbers, particularly during convalescence from one of the latter patients. It is of interest that in Patient 1 who yielded no significant pathogens, and in the four patients in whom *Staph aureus* predominated pneumonia began either on the same day (three cases) or within two days of the onset of influenza.

There was slight to moderate leucocytosis with polymorphonuclear predominance during the febrile stage of the pneumonia in eight of these patients. In the other three the total counts averaged between 4 000 and 9 000, the lowest counts being obtained in one of the patients with staphylococcal pneumonia. Blood cultures were negative in all of the eleven patients and cold agglutinins could not be demonstrated in any of the sera. All but two of the patients were treated with sulfadiazine or penicillin or both, and the response to this treatment varied from fair to excellent. All recovered without complications.

The serologic findings in these cases were similar in every respect to those found in uncomplicated cases of influenza B which were studied at the same time¹⁶⁻¹⁷. The initial titers of influenza B antibodies were low in every subject except Patient 5, and in that patient the initial serum was obtained eight days after the onset of influenza. In every case including Patient 5, there was at least a fourfold and usually a much greater rise in titer of influenza B antibodies demonstrable by both the agglutinin inhibition and complement fixation tests. Similar results were obtained with the Lee strain and with the two recently isolated strains in the sera of four patients who were tested with all three strains.

None of these patients showed a significant rise in titer of antibodies to PR8. Agglutinin inhibition titers of 64 or higher were found in the sera of four of the patients and complement fixation titers of 32 or higher were obtained in the sera from these four patients only.

The time relationships between the influenza B antibody response and the onset of the infections in three patients are worthy of comment. In Patient 9 the initial titers of agglutinin inhibition of the influenza B viruses were all low. This serum was obtained thirteen days after what was considered to be the onset of clinical influenza. A significant rise in these antibodies was demonstrated in serum obtained five days later, or eight days after the onset of the pneumonia. Since rises in titers have usually been found in adults by the eighth day these findings suggest the possibility that the initial illness either was not influenza B or else it failed to elicit an antibody rise until after pneumonia began. The findings in Patient 10 were similar but in this case there were significantly elevated titers of PR8 antibodies in the initial serum which was obtained ten days after the onset of influenza and five days after what was considered to be the onset of pneumonia. The rise in B antibodies was demonstrated in serum obtained five days later. In Patient 11 there were two illnesses six weeks apart and from the history both were considered to be clinical influenza. The pneumonia began on the same day as the second attack and the rise in influenza B antibodies occurred between three and eleven days later.

Group II. Patients With Serologic Evidence of Recent Infection With Influenza B.—There were twenty-five patients in this group (12 to 36 in Table I). Thirteen were men and twelve were women and they ranged in age from 13 to 80 years. A history considered to be that of clinical influenza was obtained in

[illegible][illegible]

nineteen of these patients, including one who had two similar attacks three weeks apart, two others had an illness which was more like a common cold, while no history of an antecedent illness distinguishable from pneumonia could be elicited in the four remaining patients. The onset of these illnesses occurred between December 3 and January 12, and in all but three instances they began between December 15 and January 5.

The interval between the onset of influenza or cold and pneumonia was seven days or less in twelve cases and from eight to fourteen days in eight others. The pulmonary lesion in thirteen patients was that of typical lobar pneumonia involving a single lobe or two contiguous lobes. Pneumococci predominated in cultures of the sputum in eleven of these patients and were also grown from the blood of four of them, in one of the latter the sputum cultures yielded predominantly *Staph aureus* during convalescence. Cultures of sputum in one instance yielded only alpha hemolytic streptococci, and none were made in one case.

The remaining twelve patients had atypical pulmonary lesions which involved chiefly a single lobe in five, two contiguous lobes in two, and both lungs (mostly the lower portions) in the other five. *Staph aureus* was obtained from a blood culture of one of these patients and was predominant in the sputum cultures of two others, including one which yielded pneumococci as well, beta hemolytic streptococci were the predominant organisms in the sputum in two patients and pneumococci predominated in two others. Cultures in the remaining five cases were either inadequate or yielded no significant pathogens.

The leucocyte counts were elevated during the febrile course in most of the patients with atypical pulmonary lesions and were similar in those with lobar and atypical pneumonia. Total counts of 8,000 or lower were obtained some time during the febrile course in two of the former and in three of the latter. In the others the total counts ranged between 12,000 and 40,000, with polynuclears predominating in every instance. None of the patients in this group showed elevated titers or rises in titers of cold agglutinins.

All but one of the patients in this group were treated with sulfadiazine, penicillin, or both and responded favorably to this treatment. They all recovered and became essentially afebrile within twenty-four to seventy-two hours after the treatment was started.

The initial serums were obtained in almost all of these cases between the sixth and fourteen day after the onset of the initial illness and within the first week after the onset of the pneumonia. The titers of influenza B antibodies in these initial sera were significantly elevated and about equally so in both tests and for each of the B strains used. There were six patients in whom there were suggestive or definite rises in these titers on repeated tests with one or more of the B strains. The initial serum in four of these six patients was obtained on or before the seventh day after the onset of clinical influenza. In three other patients the later sera showed a definite drop from high titers, the initial serum was obtained on the twelfth day in one and on the thirteenth day in the second, while the third patient had two distinct illnesses which began twenty-seven and five days, respectively, before the first blood was taken. In the latter case a suggestive drop was noted in the titer of the second blood obtained ten days after the first one.

No significantly elevated titers or rises in titers of antibodies to the PR8 strain were obtained in this group except in Patient 31. In this patient a slightly greater than fourfold rise was elicited by the agglutinin inhibition tests, while the complement fixation tests with the same virus yield low titers and no rise.

Group III Patients Lacking Serologic Evidence of Influenza Virus Infection—The relevant findings in thirty-three such patients are listed in Table II. The clinical features of this group resembled those of the two previous groups in some respects but showed some important points of difference. The age distribution, for example, was similar but the sex distribution in the present cases differed from that of the other groups and was more like that usually found in acute bacterial pneumonias in adults. The patients ranged in ages from 14 to 75 years and there were twice as many men as women.

A larger proportion of the antecedent illnesses in this group were simple colds. Thus, of twenty-nine patients from whom a history of antecedent illness distinct from the pneumonia could be elicited, that illness was classified as clinical influenza in twelve as a cold in twelve, and as a cold followed five to twenty-six days later by clinical influenza in five. The interval between the onset of the illness that was characterized as clinical influenza and the onset of pneumonia was two days or less in twelve cases and five to ten days in five cases. The interval between the onset of the cold and that of the pneumonia was less than two days in only two patients but five to ten days in six and eleven to twenty-eight days in eight.

The pulmonary lesion was classified as typical lobar pneumonia in nineteen patients, involved a single lobe in fourteen and two contiguous lobes in the other five. The predominant organism in the sputum was *Staph aureus* in one of these patients and the same organism was obtained from the blood culture of that patient. pneumococci predominated in the sputum of seventeen including one with a positive blood culture, and the bacteriology was inadequate in one case.

The remaining fourteen patients had atypical pulmonary lesions involving mostly the lower portions of the lung—one side in eight and bilaterally in six. The predominant organisms varied more than among the lobar pneumonias. *Staph aureus*, beta hemolytic streptococci, pneumococci, and Friedlander's bacilli each were found in two or three cases alone or in combination with one of the others. A positive blood culture for hemolytic streptococci was obtained in one case. In two patients no adequate bacteriological studies were made and in three others the sputum cultures yielded predominantly alpha hemolytic streptococci but no significant pathogens.

Cold agglutinins were demonstrated (a rise from < 10 to 80) in one of the latter but in none of the other thirty-two patients in this group. The leucocyte counts during the febrile period in this group were similar to those found in the other groups. Total counts of 5,000 or less were obtained in three cases, between 6,000 and 10,000 in six and from 11,000 to 28,000 in the others. Sulfadiazine, penicillin or both were used in the treatment of all but three of these patients with good effects in most instances. There were two deaths in this group, one a 75-year-old patient with pneumococcal pneumonia complicated by congestive heart failure (Patient 61) and the other a 65-year-old patient with Friedlander's pneumonia.

Ireland	11/6	<10	12/9	80
Collected after				

determinations were drawn immediately prior to initiation of dietary deficiency, just before infection, and two, five, ten, fourteen, twenty one, twenty eight and forty two days after infection. Twenty eight days after infection all animals were injected subcutaneously with *S typhimurium* O antigen. The immune response was determined two weeks later. Antibody titers and electrophoretic distributions of plasma proteins were measured concurrently on the twenty eighth and forty second postinfection days. The experiment was terminated on the forty second postinfection day, forty eight days after protein deficiency was started and fifty eight days after the experiment began.

Young, growing, male, Sherman strain rats weighing 60 to 70 grams were used. In this study, four experimental groups were established as follows:

	WELL NOURISHED	PROTEIN DEFICIENT	TOTAL
Infected	20	18	
Noninfected	10	12	
	—	—	
	30	30	60

The animals were isolated in an air conditioned room and kept in individual wire cages on wide meshed wire bottoms. The diets used had the following composition:

DIET COMPOSITION PER 100 GM RATION

FOOD	ADEQUATE RATION	PROTEIN DEFICIENT RATION
Casein	18 Gm	2 Gm
Sucrose	73 Gm	80 Gm
Mazola	5 Gm	5 Gm
Phillips and Hart salts IV ²⁰	4 Gm	4 Gm
Cystine	0.2 Gm	0.2 Gm
Thiamine chloride	200 gamma	400 gamma
Pyridoxine	200 gamma	400 gamma
Riboflavin	400 gamma	800 gamma
Niacin	25 mg	50 mg
Calcium pantothenate	15 mg	30 mg
Choline chloride	100 mg	200 mg
Inositol	100 mg	200 mg
Biotin	50 gamma	100 gamma

Haliver oil was fed in 0.1 cc amounts biweekly, water was offered ad libitum. Diets were isocaloric, providing 4.1 calories per gram ration. The 18 per cent casein diet afforded 155 to 368 mg nitrogen per twenty four hours, depending upon consumption, the 2 per cent casein diet, 19 to 39 mg nitrogen per twenty four hours. Twenty four hour food consumption was recorded biweekly.

The stock culture of the infecting organism, *S typhimurium* (*Bacillus aertrycke*), was originally isolated from a mouse epizootic and subsequently maintained in a frozen state on an agar slant*. This organism was characterized by smooth, pearly white, small, elevated colonies which produced acid and gas with mannite, dextrose, maltose, arabinose, inositol, sorbitol, and rhamnose and in Russell double sugar media, lead acetate was reduced, no reaction occurred with lactose, sucrose, or xylose. Subcultures at 37° C in tryptic digest broth were made sequentially at twenty four, twenty four, eighteen, and six hours. Diluted aliquots of the final, young, six hour subcultures were injected. In the preliminary studies a 10⁻³ (1:1,000) dilution was found to provide a 50 per cent lethal intraperitoneal inoculum. In this experiment, 1 ml of a similar dilution containing 300,000 viable cells per milliliter was used in an endeavor to provide a 100 per cent infection rate without subsequent mortality.

At previously noted intervals, 1 ml of blood was obtained by heart puncture under light ether anesthesia. Sterile technique was used. An initial 0.1 ml of the sterile sample was placed in blood culture tubes containing 5 ml freshly prepared tryptic digest broth. The remainder of the sample, placed in small tubes containing 0.2 mg dried heparin, sufficed for all except electrophoretic determinations.

*We are indebted to Dr. John Enders for the stock culture used.

on January 25, February 1, and February 2, respectively. The onset of the pneumonia was on February 12 in the first, February 6 in the second, and February 2 in the third. No significant bacterial pathogen was obtained in the first case, clinically that case resembled primary atypical pneumonia. The other two were typical cases of pneumococcal lobar pneumonia due to type 5 and type 4 pneumococcus, respectively.

Another interesting feature of the present cases was the difficulty sometimes encountered in differentiating between the onset of the influenza and that of the pneumonia. Indeed in some of the cases the onsets, at least from a clinical point of view, occurred almost simultaneously. In the others varying intervals elapsed before the pneumonia began but these intervals were usually shorter after illnesses that were characteristic of clinical influenza than they were after illnesses that resembled the common cold. That seemed to be true irrespective of whether or not the clinical influenza was associated with an antibody response to the virus.

The significance of the findings of evidence of influenza virus infection with respect to the occurrence, incidence, or severity of bacterial and other pneumonias is by no means clear. The findings in some cases suggest that the pulmonary lesion is due primarily, if not entirely to the virus but such cases are rare. In most of the cases, the character of the pulmonary lesion, the clinical course of the disease, and the response to antibacterial therapy is characteristic of infection with the predominant bacteria found in the sputum or lungs and does not seem to be markedly influenced by the antecedent influenza virus infection. Some cases, particularly those in which hemolytic *Staph aureus* is the predominant or only bacterial invader, may be exceptions.

The situation may be different under other conditions, such as those which prevailed during the influenza pandemic of 1918. The nature of the primary etiologic agent of that pandemic is not known but the incidence and severity of the complicating pneumonias at that time were different from those encountered during any of the epidemics which were known to be caused by varieties of influenza A or B. A close resemblance however was demonstrated between the staphylococcal pneumonias which occurred during the influenza A outbreak of 1940-1941 and the pulmonary complications that occurred in certain circumscribed areas during the pandemic.^{3,4} There are very little data available from which one may determine whether the nature of the virus or of the bacteria or the proper combinations of virus and bacteria were responsible for some of the varieties of pneumonia that were encountered during that great pandemic.

SUMMARY AND CONCLUSIONS

Some of the relevant clinical findings in sixty-nine cases of bacterial and other pneumonias that were studied during and shortly after the epidemic of influenza B which occurred in Boston in December 1945, are presented. Serologic tests for antibodies to influenza A and B viruses including two epidemic strains of the latter were carried out in sera obtained from these patients during and after the acute phase of the pneumonia.

About one half of the cases that occurred during the period of epidemic prevalence of influenza B irrespective of the clinical character of the pneumonia

of the bacteriologic findings, yielded serologic evidence of infection with influenza B virus. Almost all of the patients from whom serologic evidence of influenza B infection was obtained had an illness which was characteristic of clinical influenza, that illness began either at about the same time as the pneumonia or within a few days previous to the onset of pneumonia.

INTRODUCTION

THE relationship between hunger, famine, and infection¹ has become more conspicuous by reiteration than by demonstration. Each newly isolated nutritional factor has been indicted for some inadequacy of infectious disease response.² In recent years, protein nutrition, in particular, has acquired considerable prominence in this regard. It has been inferred that protein inanition would increase susceptibility or decrease resistance to infectious disease by altering protective responses.³⁻⁴ Clinical observations⁵⁻⁷ and specific laboratory investigations⁸⁻¹⁶ have somewhat implemented this hypothesis.

In general, laboratory studies pertaining to response to infection associated with protein deficiency have measured phagocytic indices,¹²⁻¹³ humoral antibody titers produced by a nonpathogenic antigen,^{10-12, 14-15} or a lethal end point produced by a virulent, viable pathogen.^{8-9, 11-16} Concomitant studies of variations in specific physiologic responses to diet and infection have been rather limited.¹⁷⁻¹⁹ The response of an organism to infection under any imposed condition is characterized by many adaptative phenomena. To further test the implications of protein deficiency and infection, observations of several simultaneous physiologic adaptations to controlled dietary deficiency and specific infection are necessary. To this end, data are presented indicating growth, food consumption, concentration, total circulating and electrophoretic distribution of plasma protein, and bacteriologic, immunologic and hematologic studies in control and *Salmonella* infected rats, both well nourished and protein deficient.

METHOD

After an observation period on adequate or protein deficient diets, animals were infected with virulent *Salmonella typhimurium*. Controls with regard to diet and infection were maintained. Preliminary experiments involving sizable groups of rats were performed to determine the 50 per cent lethal dose of viable pathogen, the incidence and duration of bacteremia, the alteration in leucocyte, hemoglobin and plasma protein concentrations associated with infection and adequate or deficient diet and the general trend of antibody titers. These studies were done before and one, three, seven, fourteen, twenty one, and twenty eight days after infection. The more extensive study comprising this report was based upon the unreported data of these preliminary experiments. In this study, blood samples for the various

Received for publication Oct. 30, 1947.

determinations were drawn immediately prior to initiation of dietary deficiency, just before infection, and two, five, ten, fourteen, twenty one, twenty eight and forty two days after infection. Twenty eight days after infection all animals were injected subcutaneously with *S. typhimurium* O antigen. The immune response was determined two weeks later. Antibody titers and electrophoretic distributions of plasma proteins were measured concurrently on the twenty eighth and forty second postinfection days. The experiment was terminated on the forty second postinfection day, forty eight days after protein deficiency was started and fifty eight days after the experiment began.

Young, growing, male, Sherman strain rats weighing 60 to 70 grams were used. In this study, four experimental groups were established as follows:

	WELL NOURISHED	PROTEIN DEFICIENT	TOTAL
Infected	20	18	
Noninfected	10	12	
	<hr/> 30	<hr/> 30	60

The animals were isolated in an air conditioned room and kept in individual wire cages on wide meshed wire bottoms. The diets used had the following composition:

DIET COMPOSITION PER 100 GM RATION

FOOD	ADEQUATE RATION	PROTEIN DEFICIENT RATION
Casein	18 Gm	2 Gm
Sucrose	73 Gm	89 Gm
Mazola	5 Gm	5 Gm
Phillips and Hart salts IV ²⁰	4 Gm	4 Gm
Cystine	0.2 Gm	0.2 Gm
Thiamine chloride	200 gamma	400 gamma
Pyridoxine	200 gamma	400 gamma
Riboflavin	400 gamma	800 gamma
Niacin	2.5 mg	5.0 mg
Calcium pantothenate	1.5 mg	3.0 mg
Choline chloride	100 mg	200 mg
Inositol	100 mg	200 mg
Biotin	50 gamma	100 gamma

Haliver oil was fed in 0.1 cc amounts biweekly, water was offered ad libitum. Diets were isocaloric, providing 4.1 calories per gram ration. The 18 per cent casein diet afforded 155 to 368 mg nitrogen per twenty four hours, depending upon consumption, the 2 per cent casein diet, 19 to 39 mg nitrogen per twenty four hours. Twenty four hour food consumption was recorded biweekly.

The stock culture of the infecting organism, *S. typhimurium* (*Bacillus aertrycke*), was originally isolated from a mouse epizootic and subsequently maintained in a frozen state on an agar slant*. This organism was characterized by smooth, pearly white, small, elevated colonies which produced acid and gas with mannite, dulcitol, maltose, dextrose, arabinose, inositol, sorbitol, and rhamnose and in Russell double sugar media, lead acetate was reduced, no reaction occurred with lactose, sucrose, or xylose. Subcultures at 37° C in tryptic digest broth were made sequentially at twenty four, twenty four, eighteen, and six hours. Diluted aliquots of the final, young, six hour subcultures were injected. In the preliminary studies a 10⁻³ (1:1,000) dilution was found to provide a 50 per cent lethal intraperitoneal inoculum. In this experiment, 1 ml of a similar dilution containing 300,000 viable cells per milliliter was used in an endeavor to provide a 100 per cent infection rate without subsequent mortality.

At previously noted intervals, 1 ml of blood was obtained by heart puncture under light ether anesthesia. Sterile technique was used. An initial 0.1 ml of the sterile sample was placed in blood culture tubes containing 5 ml freshly prepared tryptic digest broth. The remainder of the sample, placed in small tubes containing 0.2 mg dried heparin, sufficed for all except electrophoretic determinations.

*We are indebted to Dr. John Enders for the stock culture used.

Blood cultures were incubated for twenty four hours at 37 C. Positive growths were plated out on eosin methylene blue and blood agar plates, the small violet and small pearly white colonies respectively, of gram negative bacilli were appropriately identified. All negative cultures were kept five to seven days before being discarded.

Hemoglobin (oxyhemoglobin) was determined in the Klett Summerson photoelectric colorimeter, using a 540 m μ filter, and the relative cell volume was calculated from it.²¹ Total plasma protein concentration was determined gravimetrically by the copper sulfate method, using the formula: Total protein (gm/100 cc) = $389.6 (Gp - 100.9)^2$. Total leucocyte and differential counts were done by the usual methods. Blood volume partition studies, using Evan's blue dye T 1824 and a modified single sample photoelectric micro colorimetric technique,¹ were done concurrently with the concentration determinations at several intervals. Total circulating hemoglobin and total circulating protein were readily calculated and adjusted to unit values (grams per unit blood or plasma volume). These unit values were derived by adjusting total volumes to a unit of surface area (milliliters per 100 cm²).²² Surface area was calculated according to the formula: SA (cm²) = $12.54 (\text{weight})^{0.6624}$.

Humoral group and type specific antibody titers were determined by a standard two fold eight tube serum dilution agglutination method. Five tenths milliliter of a 1:10 plasma mixture and 0.5 ml of the appropriate antigen were used in the first tube. The formalin treated, diluted suspension for floccular agglutination (H or flagellar antigen) and the alcohol treated, diluted suspension for granular agglutination (O or somatic antigen) were prepared from the original *S. typhimurium* inoculum by standard Massachusetts State Laboratory procedures.

Several animals of each group were sacrificed by heart puncture on the twenty eighth postinfection day, at the time of subcutaneous injection of O antigen in the remaining rats. Sera from the sacrificed animals were pooled by group for electrophoretic analyses. Electro phoreses of the sera were carried out in a modified Fischel's apparatus.* Three to five milliliters of serum were diluted to 12 ml giving approximately 2 per cent protein concentration and subsequently dialyzed against sodium diethyl barbiturate buffer of pH 8.6 and 0.1 ionic strength. A 10 ml cell was used and runs of 7,200 seconds were made at 1 to 2 C and potential gradients of 5 to 6 V per centimeter. Photographs of schlieren patterns obtained with a cylindrical lens at an angle of 45°, were made and enlarged 1.5 by projection. Mobilities were calculated from descending boundary patterns. Relative proportions of the various plasma components were determined by planimetry of Gauss curve resolved areas. The reported compositional data represent an average derived from both ascending and descending boundary patterns, excluding the delta and epsilon boundary anomalies.

At time of death, bone marrow imprints²⁶ were obtained from the distal diaphysial third of the left femur, eight to ten consecutive imprints were made on each of three coverslips. A modified May Grunwald Giemsa stain was used. Each of one hundred adjacent cells derived from a well defined peripheral area of five consecutive imprints was identified and tabulated. Cytologic classification followed that of Straney and Higgins⁶ but megakaryocyte, myeloblast, promyelocyte, myelocyte, metamyelocyte, granulocyte, lymphoblast, lymphocyte, plasma cell, reticulum cell, erythroblast, pronormoblast, normoblast and unclassified cells were enumerated. To simplify evaluation these were grouped as immature myeloid forms, mature granulocytes, erythroblasts, normoblasts, lymphocytes, and other miscellaneous cells. Total marrow cellularity was not estimated.

RESULTS

Results are summarized in Tables I through VI and Figs 1 through 3.

Growth —

DISCUSSION

Caloric and Nitrogen Consumption Weight increments of 3 to 5 Gm per day on the initial control diet represented an adequate growth rate for rats of

*According to the technique of the Department of Physical Chemistry.²³

Fig 1—Relative average food consumption of control and infected rats on 18 per cent and 2 per cent protein diets. Total ration consumed as measured over a twenty-four hour period is compared with caloric and nitrogen intakes adjusted to a unit of body size

this age, sex, and strain, and for this diet. Progressive weight loss, ultimately amounting to 20 to 25 per cent of the starting body weight, attended protein deficiency. Growth responses to the 18 per cent and 2 per cent casein diets are indicated in Fig 1. Total food consumption per twenty-four hours per rat was greater in the well-nourished than in the deficient animals (10 to 15 Gm per twenty-four hours versus 6 to 10 Gm per twenty-four hours). The relative

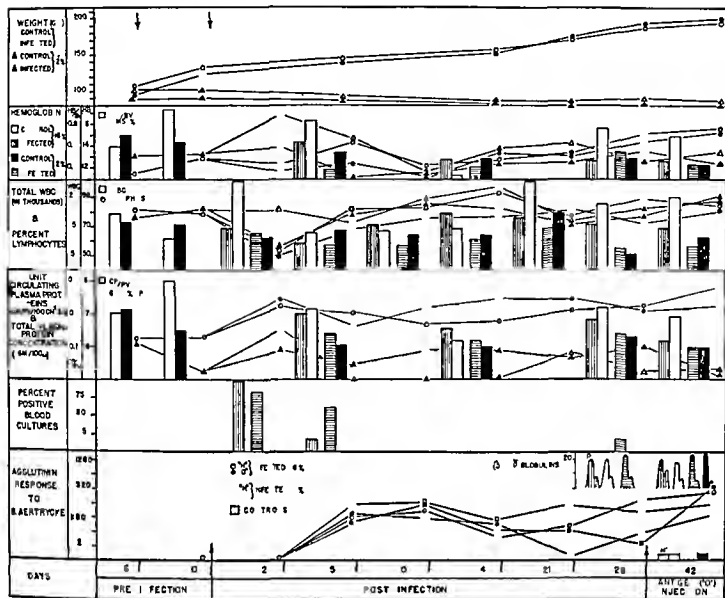

Fig —Summary of the blood and bacteriologic findings in control or *Salmonella* infected rats on 18 per cent or 2 per cent protein rations

caloric consumption per 100 Gm rat per twenty four hours however, was similar in both groups. During some phases of the study the protein deficient animals appeared to consume more calories per 100 Gm rat than did the well nourished animals. Irrespective of infection well nourished animals consumed 155 to 368 mg N per 100 Gm rat per twenty four hours and deficient animals 19 to 39 mg N per 100 Gm rat per twenty four hours (Fig 1). The similarity of nitrogen consumption in the infected and noninfected animals and the lack of striking differences (irrespective of dietary protein level) in caloric intakes per 100 Gm rat per twenty four hours serve in lieu of pair fed nutrition control data. Nitrogen consumption of the animals receiving an adequate diet appeared to be inversely proportional to growth and unaltered by infection. Nitrogen consumption of the deficient animals was maintained at a relatively constant level despite both infection and progressive weight loss.

Blood Studies —

Hemoglobin Hemoglobin concentration values in grams per 100 ml for rats of this race strain and sex range from 12.20 ± 0.9 to 15.1 ± 0.3^2 and are similar to values reported for other strains. Hemoglobin concentrations of infected and noninfected animals followed similar trends. Differences between

well-nourished and deficient animals were apparent only shortly after infection was initiated and again forty-two days later as the experiment was concluded. The immediate postinfection period was accompanied by higher hemoglobin concentrations in the infected and control protein-deficient animals (Table I). Hemoconcentration attending this phase of acute protein deficiency would seem to account for the high levels noted and serve to mask a suggestive depletion of unit circulating hemoglobin in the protein deficient groups^{28, 29} (Table II, Fig 2). However, a consistent relationship between hemoglobin concentration and unit circulating hemoglobin was not demonstrable during this early phase of rapid adjustment to infection and diet. At twenty-eight and forty-two days after infection, both hemoglobin concentrations and unit circulating hemoglobin levels appeared to be diminished in the protein-deficient animals, without significant difference being imposed by infection. This finding would seem compatible with the observed anemia associated with long-continued low casein diets²⁸⁻³¹ and is possibly related to impaired globin formation. The decreased unit circulating hemoglobin of the well-nourished infected animals was masked by the decreased plasma volume and resultant apparent hemoglobin concentration. With the exception of a probable technical error on the fourteenth postinfection day, the circulating hemoglobin of the uninfected, well-nourished rats was somewhat greater than that noted in the other groups. The relative anemia of the well-nourished infected animals may represent an anemia of infection, presumably related to hypoferrinemia³².

Total Leucocyte and Differential Counts Reported values for total leucocyte and differential counts in rats approximate 8 to 15,000 white blood cells per cubic millimeter, of which 4 to 25 per cent are polymorphonuclear granulocytes, the remainder, largely lymphocytes²⁷. Infected and control animals on the 2 per cent protein diet manifested an absolute leucopenia after approximately three weeks of dietary deficiency. Leucopenia¹³ and granulocytopenia³³ have been observed to attend protracted dietary protein restriction. Well-nourished uninfected rats appeared to have the highest total white blood cell counts after the second post-infection week. No other striking differences in total white blood cell counts of the various experimental groups were evident. Relative lymphopenia was observed in both groups of infected animals forty-eight hours after infection was initiated. The 18 per cent control value inadvertently represented a single animal observation. With this possible exception, the immediate post-infection lymphopenia would seem to be in accord with the alarm reaction phase of the general adaptation syndrome of Selye^{34, 35} and may have represented a period of rapid lymphocyte dissolution with attendant elaboration of antibody globulin^{36, 37} in both groups of infected rats, although no antibody titers were demonstrable at that time.

Hematopoiesis Peripheral blood leucocytes and hemoglobin variations were associated with suggestive hematopoietic changes in the femoral bone marrow. The distribution of cellular elements in the femoral marrow of the twenty-seven well-nourished and twenty-five deficient rats examined was similar to that reported in twenty-four Wistar strain²⁶ and twelve Rockland strain rats³⁸. Protracted protein deficiency was associated with a tendency toward a relative

Cytologic differentiation in general followed that of Stansley and Higgins. We are indebted to Dr. A. Lapi and to Miss Doris Wilson for assistance with the counts. With the exception of lymphocyte counts consistent definition was achieved. Immature myeloid forms include myeloblasts, promyelocytes, myelocytes, metamyelocytes, normoblasts include pronormoblasts, metamyelocytes, myelocytes, plasma cell, reticulum cells, megakaryocyte, and undifferentiated cells.

*The majority of the low lymphocyte counts in the forty two day postinfection groups were recorded by one observer.

increase of immature myeloid forms without apparent increase in mature granulocytes, either in the marrow or peripheral blood. This may have been a compensatory response to peripheral leucopenia, or might suggest a granulocyte maturation inadequacy or arrest. Depletion or inhibition of some factor necessary for production of the mature granulocyte may have been responsible. The phenomenon appeared to be associated with dietary protein deficiency irrespective of infectious status. Fewer maturing erythroid forms, particularly normoblasts, were noted in the deficient rats. The diminished erythropoietic activity of the protein deficient rat may have resulted from inadequate globin formation and may have been partially responsible for the observed depletion of unit circulating hemoglobin. At the level of hemoglobin synthesis attained, hypoferrremia associated with infection³² appeared to be a less important limiting factor. The tendency of infected well-nourished animals toward a larger proportion of erythroid forms than the uninfected controls might reflect a compensatory response to relative depletion of unit circulating hemoglobin. Presumably adequate globin synthesis occurred on an 18 per cent casein diet. Accordingly, at the level of hemoglobin synthesis in the well-nourished infected rat, hypoferrremia may have been a limiting factor and partially responsible for the observed depletion of unit circulating hemoglobin.

Hematopoiesis, as reflected in the femoral marrow myeloid-erythroid differences, appeared to be more influenced by diet than by infection. The immune response observed at forty-two days postinfection did not appear to be associated with distinct variations in the femoral bone marrow picture in any of the groups.

Plasma Proteins Total plasma protein concentrations in rats of this age, sex, and strain vary from 6.60 ± 0.1 to 8.07 ± 0.07 ^{23, 39}. In this particular experiment, the total plasma protein concentration appeared to reflect the level of protein nutrition of the animal. In general, however, the measurement of concentration provides an inconsistent indication of total circulating proteins owing to plasma volume variations^{40, 41}. Protein deficiency per se is attended by significant decreases in unit circulating plasma proteins^{25, 29, 42, 44} (Fig. 2, Table I). Infection per se did not appear to induce significant change in total plasma protein concentrations. However, the unit circulating proteins of the infected rats on the 18 per cent protein diet were somewhat reduced after twenty-eight to forty-two days, in comparison with the appropriate controls, but exceeded those of the protein-deficient animals. Both groups of deficient animals had similar unit circulating protein levels.

Infection per se appeared to be associated with minimal change in plasma protein concentration, unit circulating protein, and electrophoretic plasma protein components. The electrophoretic distribution of plasma components, like the other protein measurements, varied with the dietary status. Fairly adequate resolution of the major plasma protein components (albumin, alpha, beta plus fibrinogen, and gamma globulins) was possible with a diethyl barbiturate buffer at pH 8.6, under the conditions of electrophoresis. More detailed differentiations of alpha-1 and alpha-2 globulins and of alpha-2 and beta globulins were less satisfactory. However, assuming six components, Gauss probability curves were con-

TABLE IV ELECTROPHORETIC MOBILITIES OF WELL NOURISHED AND PROTEIN DEFICIENT RATS

Mobilities calculated from descending boundary patterns only according to the formula $\Delta h \times \frac{1}{T \text{ sec (Milliamperes)}}$ (0.5) hence all values represent $M \times 10^5$. The lower values in the range of per cent diet plasma mobilities are contributed entirely by the 2 per cent control group after twenty eight days of diet deficiency. This analysis was run some months after those of the seven other groups. All means are weighted by relative numbers of animals per group contributing to the value.

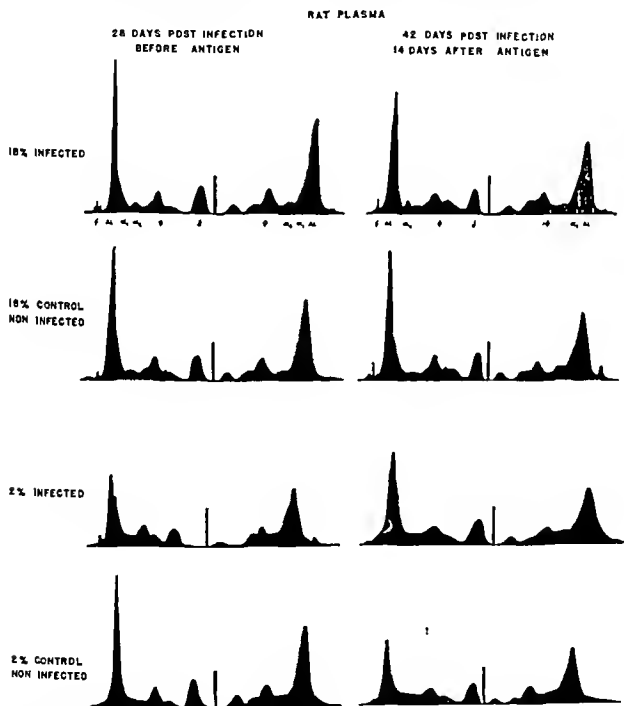

Fig. 3—Schlieren patterns of the electrophoretic analyses of rat plasma pools derived from infected and noninfected rats on 18 per cent and 2 per cent protein ration. Both ascending and descending boundary patterns are shown twenty-eight days after infection (prior to antigenic stimulation) and fourteen days later following the injection of *S. typhimurium* O antigen. All determinations were made using a sodium diethyl barbiturate buffer at pH 8.6 and 0.10 ionic strength. The 2 per cent diet infected preantigen pattern and the 2 per cent diet control postantigen pattern represent protein concentrations of 1 and 1.4 per cent respectively. The remainder of the patterns represent analyses at 2.0 ± 0.1 per cent protein concentrations.

*Somewhat arbitrary values derived from relative areal resolution and representing average per cent.

†Derived from the product of the plasma protein concentration of the pool and the per cent of the resolved schlieren pattern.

‡Represents the product of the average unit circulating proteins (Table II) derived from the resolved schlieren pattern.

§Two per cent control calculations were derived from electrophoretic runs carried out several

sistently and reasonably, if somewhat arbitrarily, drawn. Separation of beta-1 and beta-2 globulins was not entirely satisfactory in these analyses, although distinct demarcations were apparent in some instances. Beta-2 globulin and fibrinogen were not separated under the conditions of electrophoresis and, accordingly, were considered together. Gamma globulin was quite distinct in all patterns and was well separated from the boundaries. A so-called "f" component with mobility greater than that of albumin has been noted in rat plasma⁴⁵ and consistently appeared in our patterns. Its significance is not known. The mobilities of the various components (Table IV), calculated from the descending patterns, are similar to those reported for other rats^{45, 46} and roughly approximate the mobilities of human plasma components.

The plasma composition is indicated in Table V. Typical patterns are illustrated in Fig. 3. Since all electrophoretic data were derived from pooled samples, the range and standard deviation of individual rat variation were not evident. The composition of rat plasma appears to vary with the strain used.⁴⁶ Previous reports have been largely concerned with the Long-Evans^{46, 47} or Sprague-Dawley strains.⁴⁸ In the Sherman strain rat used in this study, the plasma composition was similar to that observed in man,^{48, 50} gamma globulin values were slightly lower.

Concentrations of the various plasma components were calculated from the proportionate composition of schlieren patterns and the total plasma protein concentrations of the respective pools. Since unit circulating protein data appear to be more reliable than simple concentration measurement as an indicator of plasma protein variation, the total circulating amount of each plasma component in the vascular compartment was also calculated and adjusted to unit value. Such arbitrary calculation was dependent on resolution of electrophoretic

components, plasma protein concentrations, and mean unit plasma volumes (Table V). Accordingly, these data are more relative than absolute, owing to limitations in the various techniques employed. The results remain proportional, however, since the error was systematic.

Severe protein deficiency protracted for four to six weeks resulted in a considerable decrease in total plasma protein concentration and in unit circulating protein. This diminution in protein usually has been considered the result of albumin depletion.^{43, 44} In the electrophoretic patterns as noted by Bielecki and co-workers,⁵¹ nutritional hypoproteinemia did not appear to be characterized by a marked decrease in the proportionate area representing albumin. However, with calculation of the relative concentration (grams per 100 cc) of the various electrophoretic plasma protein components it was evident that protein deficiency was characterized by a reduction in electrophoretic albumin as had been noted in dogs.^{52, 4} Albumin depletion appeared more marked when interpreted in relation to the associated diminished plasma volume (unit circulating plasma protein composition).^{*} The proportion of the pattern and the concentration of alpha and beta globulins appeared slightly increased in the hypoproteinemic rats. This observation is in general accord with that of Chow.⁵⁴ When adjusted to unit plasma volume, no distinct difference between circulating alpha and beta globulins in the well nourished or deficient animals was noted. The most marked electrophoretic change induced by protein deficiency was the reduction in both concentration and unit circulating amounts of gamma globulin. This relative depletion was most evident, as might be expected after six weeks of severe protein deficiency. No significant change in gamma globulin in

* The relatively high albumin of the noninfected rats on the twenty eighth day of the per cent protein diet remains unexplained. This run, having the slowest mobilities of the series was made several months after the other determinations.

response to infection per se was noted in the electrophoretic patterns of either the well-nourished or deficient groups

Bacteriologic and Immunologic Responses—Infection following inoculation with *S. typhimurium* was corroborated by blood culture. The time incidence and duration as observed in the 114 animals comprising this and the preliminary experiments were somewhat variable in individual animals inoculated with the same initial dose of organisms. In some instances bacteremia was present at twenty-four hours, in others, it did not appear until forty-eight hours had elapsed. It was demonstrable for three to ten days. In this study, blood culture of infected rats on the 18 per cent protein ration revealed demonstrable bacteremia in all those cultured at forty-eight hours. One of five protein-deficient infected animals did not have a positive blood culture at forty-eight hours. At four days one of five well-nourished and three of five deficient rats had positive blood cultures. The presence of bacteremia at twenty-eight days postinfection in a single protein-deficient animal remains unexplained. (See Fig. 2.) No cultures of the noninfected control rats were positive (Table VI).

‡O indicates somatic antigen agglutination.

§Number in parentheses indicates number of animals represented in determination when that figure differs from number indicated at top of column.

||Forty-second day titers represent determinations made fourteen days after injection of O antigen subcutaneously in all animals on the twenty-eighth postinfection day.

No very marked difference in the incidence of bacteremia was noted in the respective dietary groups. Two spontaneous deaths occurred during the postinfection phase, both were in protein-deficient rats. Only one was an infected animal and it died on the ninth postinfection and fifteenth diet deficient day. The other, noninfected, died on the twenty-seventh day of dietary deficiency. In preliminary experiments, an approximate 50 per cent mortality was observed in both diet groups. The majority of those spontaneous deaths occurred before the third postinfection day in the deficient rats. In the well-nourished rats,

sporadic deaths were noted over a ten day period. The low mortality of this study would appear to be the result of the relatively small inoculum of viable cells. The host¹⁸ and pathogen⁵⁵ variation from experiment to experiment cannot be adequately evaluated. The route of infection appears to be of considerable importance in relation to the subsequent clinical course. In per os infections with *S. typhimurium* demonstrable bacteremia rarely occurs. Extension of infection is largely lymphatic. Diarrhea may characterize the clinical course. With intraperitoneal inoculation dissemination of organisms is apparently largely hematogenous and diarrhea is not a constant finding.⁵⁶

The average agglutinin titer to somatic and flagellar antigens is tabulated according to the reciprocal of the average titer of the group (Table VI). The trend of antibody response to infection is depicted in Fig. 2. It is evident that both O and H agglutinin titers were demonstrable at five days postinfection in both deficient and well nourished rats. The highest recorded titer in both groups at that time was 1:160. Titers remained relatively constant averaging approximately 1:160 for twenty one days after infection. H agglutinin titers in both deficient and well nourished animals were somewhat higher than O agglutinins. The difference was more marked at twenty eight days, flagellar agglutinins in some instances attaining titers of 1:640 (seven tubes) in both diet groups. These data suggest that severe protracted protein deficiency per se did not impair circulating humoral antibody response to the virulent infecting pathogen used in these studies. Lack of significant difference in quantitative circulating gamma globulins in the two diet groups appears consistent with the observed antibody responses at twenty eight days after infection.

On the twenty eighth postinfection day, all animals were inoculated subcutaneously with O antigen in order to test the immune and anamnestic responses. The average response of the deficient infected animals as measured by O and H agglutinin titers was slightly greater than that of the well nourished animals. The highest titers were 1:640 and 1:1280. The increase in O agglutinin titers, corresponding to an immune response was more marked than the associated rise in H titers. The apparent immune and anamnestic agglutinin responses did not appear to correlate with the changes in quantitative circulating gamma globulin in either group. Unit circulating gamma globulin of the 18 per cent protein rats remained essentially unchanged, that of the 2 per cent protein rats was distinctly diminished, despite increased agglutinin titers in both groups. No significant differences in circulating gamma globulin were noted between infected and control animals of respective diet groups although the control groups had negligible or no agglutinin titers at either twenty eight or forty two days. These data might be consistent with observations that the O antibody to another bacterial species, *Escherichia typhosa*, is not contained in the gamma globulin fraction⁵ or that all gamma globulin is not antibody.⁸ In this regard, it is interesting that the somatic antibody is probably more closely related to protection against infection than is the flagellar antibody.⁹ The secondary rise in O titer following inoculation of type specific O antigen in the hypoproteemic rats would seem to indicate that dietary protein deficiency does not seriously impair the mechanism for protective antibody fabrication in

the rat. This finding is at variance with that reported by Cannon and co-workers^{14, 15} and Berry and associates¹² in rats, and by Klebs⁶⁰ in one patient. It is in accord with the conclusions reached by Bieler and co-workers⁵¹ with several human subjects with hypoproteinemia.

COMMENT

Protein deficiency causing inadequate response to infection would appear to be an oversimplification of a many-faceted phenomenon. An appropriate experimental procedure involving the single variable of protein deficiency has not yet been reported. The genetic status of the host¹⁶ and pathogen,⁵⁶ host factors initiating antibacterial immunity,⁵⁹ the source of protein,⁸ protein deficiency conditioning other nutritional inadequacies as for example that of maeam,⁶¹ and numerous other fundamental variables have not been simultaneously controlled. Endocrine-protein metabolic interrelationships³⁶ and coincident nitrogen balance, liver protein, and protein synthesis studies would be helpful in interpreting the place of protein in infection response.⁶²

This study represents an attempt to correlate a few related phenomena. Data derived from this and the preliminary studies manifest some degree of reproducible consistency, however, conditions attending the observations necessitate some degree of statistical inadequacy. The most satisfactory absolute measures of experimental infection with a virulent pathogen are noninfection or death—complete resistance or complete susceptibility—as specific unequivocal end points. However, physiologic variations associated with such an infection must be measured in the mid-ground between complete resistance and susceptibility, and hence are dependent upon continuity and interrupted by death. The data of this study, therefore, are not strictly comparable to those of Schneider and Webster,¹⁶ Sako,¹¹ or Watson⁸; their data were concerned with unequivocal susceptibility or resistance, this study with neither. Nor is it comparable with the data of Cannon and co-workers^{14, 15} or Berry and associates,¹² since in their studies infection was not initiated.

The response to specific *Salmonella* infection of the protein deficient rat, as demonstrated by Zilva,⁶³ Lassen,⁵⁶ and Guggenheim and Buechler¹³ and somewhat extended by this report, is apparently not markedly different from that of the well-nourished control. Physiologic variations in circulating protein observed in the *Salmonella*-infected protein-deficient rats of this experiment appear to be adequately explained by the protein deficiency per se and were comparatively uninfluenced by infection. Hematologic and hematopoietic responses, on the other hand, appear to be influenced to some extent by both diet and infection. Bacteriologic and immunologic responses, in contrast to those of the plasma proteins, did not appear to be significantly altered by protein deficiency. It is perhaps irrelevant to indicate that the crude measures of bacteremia and survival are not the only manifestations of bacteriologic response, and antibody titer does not wholly define antibacterial immunity. The multiplicity of subtle changes involved in both protein deficiency and infection precludes such oversimplification of a possible interrelationship. *Salmonella* in-

fection, for example, is presumably an intracellular infection involving mononuclear cells of lymphoid follicles. Protein deficiency of the type initiated might not sufficiently damage these cells which presumably mediate both the course of infection and antibody response.

SUMMARY

Rigid conclusions cannot be drawn from a biologic study involving isolated changing responses, rather than a specific unequivocal end point. The data presented are consistent with those observed in preliminary experiments. The data on growing Sherman strain rats subjected to infection with virulent *S. typhimurium* and to either severe protracted protein deficiency at nitrogen intakes varying from 19 to 39 mg nitrogen per 100 Gm rat per 24 hours, or adequate nitrogen intakes approximating 155 to 368 mg nitrogen per 100 Gm rat per 24 hours, may be summarized as follows:

1 Quantitative circulating plasma proteins particularly gamma globulins in both well nourished and protein deficient animals appeared to be relatively uninfluenced by infection per se despite observed changes attending protein deficiency. With protracted protein deficiency, decreased unit circulating plasma proteins, apparently representing a depletion of albumin and gamma globulin components, were observed independent of infection.

2 In both well nourished and protein deficient rats, hematologic responses as evidenced by differential bone marrow counts, total and differential leucocyte counts, and circulating hemoglobin values appeared to be altered somewhat by both infection and diet. Decreased unit circulating hemoglobin was noted in both well nourished and deficient infected rats. The diminution was somewhat more marked in the protein deficient animals. Total leucocyte counts of the deficient groups were somewhat lower than those of the well nourished. The initial postinfection relative lymphopenia manifested by both infected groups was similar.

3 Hematopoiesis, as reflected in the femoral marrow myeloid erythroid differences, appeared to be influenced more by diet than by infection. Protein deficiency was associated with a tendency toward a relative increase of immature myeloid forms and decreased numbers of maturing erythroid elements. Well nourished infected animals appeared to have a relatively greater number of maturing erythroid forms than the controls.

4 Bacteriologic and immune responses resulting from infection and secondary antigenic stimulation were essentially unaltered by severe dietary protein deficiency. No significant difference in the incidence of bacteremia was noted between infected rats on the 2 per cent or the 18 per cent casein diets. Despite relative quantitative depletion of circulating gamma globulin, protein deficient rats attained antibody titers equivalent to those of the well nourished animals in response to infection. Following specific secondary antigenic stimulation the rise in humoral antibody titer was more marked in the deficient than in the well nourished rat. Despite rise in titer no significant change in circulating gamma globulin was observed in either group.

5 In general, pertaining to the moieties tested, rats undergoing severe protein deprivation appeared to respond similarly to and as adequately as well nourished controls to infection with *S typhimurium*

We are indebted to Dr E J Cohn and Dr J L Oncley for making the Tiselius apparatus available, to Mr M Budka and Miss M Hassen for their assistance in the electrophoretic determinations, to Miss Anne Shapiro and Miss Doris Wilson for valuable assistance during the work, and to Dr Jane Worcester, Dr C A Janeway, and Dr John Enders for suggestions regarding evaluation of the data and presentation of the material

HIGH VITAMIN A INTAKE AND BLOOD LEVELS OF CHOLESTEROL, PHOSPHOLIPIDS, CAROTENE, AND VITAMINS C, A, AND I

JOHN T. VAN BRUGGEN,* PH.D. AND JOHN STRAUMFJORD, M.D.
ASTORIA, ORE.

THE literature contains several reports relating vitamin A to the blood and tissue lipids. Josephs^{1, 4} has reviewed most of the pertinent articles and from them and his own work concluded that the hypolipemia seen in a vitamin A deficient animal is due to a specific pathologic effect of an actual intestinal deficiency of vitamin A. It was found that the abrupt administration of large amounts of this vitamin caused a marked rise in total serum lipids of both normal and vitamin A deficient rats. Josephs³ suggested a simple fat solubility relationship between the vitamin and other lipids to account for this effect of vitamin A. Green,^{5, 6} in studies on serum esterase and fat absorption, and Monaghan and Schmitt, who investigated the effect of vitamin A upon unsaturated fatty acids, were inclined to relate vitamin A action to metabolic processes of essential cellular structures involving phospholipid complexes.

A number of workers have not been able to demonstrate the hypolipemia of vitamin A deficiency and the hyperlipemia of high vitamin A intake. Smith⁵ in fact, found an increase in blood fatty acids and cholesterol in deficient rats and Sure Kik and Church⁹ found no change in blood fatty acids, cholesterol and phospholipids in vitamin A deficient albino rats. Rall and Waterhouse¹⁰ found an increase of blood cholesterol in deficient dogs.

If the hyperlipemia observed by Josephs in a child⁴ and the hypercholesterolemia induced by vitamin A in the patients studied by Laseh¹¹ and Juszat¹ are a normal response in man to large doses of the vitamin then a study of this response may help to uncover the role of this vitamin in human biochemical processes. In addition, if this blood lipid response is a general phenomenon induced by ingestion of vitamin A the extent of these changes needs to be determined because of the association of hyperlipemia and hypercholesterolemia with important pathologic processes.

That vitamin A may be interrelated with a number of other vitamins is clearly pointed out in the review of this subject by Moore.¹² In the present study an attempt has been made to investigate not only the relation of vitamin A intake to blood lipid levels but also to the blood levels of several of the other vitamins interrelated with vitamin A.

General Considerations—We have had the opportunity of studying the effects of daily supplementation with 100,000 IU of vitamin A on a group of patients in the Western State Hospital†. Some of the effects of this supple-

*From the Astoria Extension Research Laboratory (Department of Biochemistry, University of Oregon Medical School).

Received for publication Oct. 9, 1944.

†Present address: Department of Biochemistry, University of Oregon Medical School, Portland, Ore.

‡The patients and facilities of the hospital at Steilacoom, Wash., were kindly put at our disposal by Dr. W. N. Keller for a long term study of the effects of vitamin A supplementation. Without the assistance of Dr. William J. Dublin and Dr. Bernice M. Hazen this work would not have been possible.

mentation on the skin of these patients will be reported by Dublin and Hazen¹⁴ The present paper is concerned with a comparative study of the blood vitamins A, E, and C, cholesterol, and phospholipid levels in a group of patients supplemented with 100,000 units of vitamin A daily and in an unsupplemented group of patients We have been unable to find in the literature any reports of work in which supplementation with large doses of vitamin A was continued over a long period of time and in which blood assays for these vitamins and for lipids were performed on a sufficient number of individuals to warrant a statistical treatment of the results

The number of patients in each group at the beginning of the study was thirty-six The patients in these groups were in similar mental and physical condition as indicated by examination and distribution curves for age, height and weight

The supplemented group received at all times the same institutional diet as the control group but, in addition, one capsule* daily containing 100,000 I U of vitamin A Determinations† of plasma carotene, vitamin A, vitamin E, free and total cholesterol, and phospholipid as well as whole blood vitamin C were done on five occasions—once before supplementation was started and after intervals of approximately eighteen, twenty-four, and thirty-six months of supplementation Additional determinations were made at forty-two months, six months after supplementation was discontinued The analyses of vitamins and lipids made at the beginning of the experiment as well as the lipid analyses at the eighteen-month period have been rejected because of unsatisfactory analytical methods

Since the blood samples were taken from the patients at Steilacoom, Wash, and a period of four to six hours necessarily elapsed before analytical work could be started in the laboratory at Astoria, Ore, the preparation and storage of blood samples will be described briefly Fifteen to twenty milliliter samples of blood were collected from each patient of a group of fifteen to twenty five patients approximately sixteen to eighteen hours after the last meal and sixteen to twenty four hours after the last dose of vitamin A Coagulation was prevented by mixing with oxalate in 30 ml centrifuge tubes dried as described by Van Bruggen¹⁵ Two milliliter samples of whole blood were immediately added to 6 ml of 6 per cent trichloroacetic acid containing nitrite After thorough mixing, the samples were stored on ice for transport The plasma from the remaining blood was separated and 1 ml was added to 24 ml of alcohol ether (3:1) in a 50 ml glass stoppered cylinder Immediately upon arrival at Astoria the trichloroacetic acid samples were filtered and the filtrates refrigerated for twenty four to forty eight hours until the vitamin C analyses could be made The alcohol ether extracts were filtered upon arrival at Astoria and analysis for cholesterol and phospholipid was begun immediately The remaining plasma was kept on ice until the analytical work for carotene and vitamins A and E had been completed These analyses were usually finished within forty eight hours

Since only twenty to twenty five blood samples could be assayed at one time, a complete assay of the two groups required three to four weeks at intervals of 0, 18, 24, 36,

*The vitamin A capsule known as Oleum A is prepared by Bioproducts Oregon Ltd Warrenton Oregon Analysis shows this product to contain the following constituents all analyses being reported as per capsule

Weight of contents 0.430 Gm free cholesterol 28 mg total cholesterol 84 mg phospholipid 0.65 mg vitamin E 0.67 mg vitamin A 100,000 I U (equivalent to 33 mg of pure vitamin A)

†We gratefully acknowledge the assistance of Distillation Products Inc Rochester N Y in the establishment of carotene and vitamin A and E methods We are especially grateful to Dr Mary L. Quail of that organization for her practical help on this problem

and 42 months, so that the time periods listed in this paper are given as approximately eighteen, twenty four, thirty six and forty two months. To insure comparable results an equal number of patients in each group was sampled at each survey trip.

METHODS

Petroleum ether extracts of 4 ml of plasma were prepared for the determination of carotene, vitamin A, and vitamin E. The plasma was well mixed with 4 ml of alcohol and then extracted once with 12 ml of purified low boiling petroleum ether. Extraction was done in a 50 ml glass stoppered cylinder by shaking for ten minutes in a horizontal position in a mechanical shaker at a speed of 160 strokes per minute with an excursion of three inches per stroke. Rotting of the cylinders for one hour insured good separation of the layers. Four milliliters of the petroleum ether extract were used for carotene and vitamin A determinations and 4 ml for vitamin E. Carotene was measured at 440 m μ and after the solvent was evaporated at 60 C under nitrogen the vitamin A was estimated by the Carr Price reaction (that is, the residue was taken up in 0.5 ml of dry chloroform, 1 drop of acetic anhydride was added and 3.5 ml of Carr Price reagent were added from an all glass apparatus that insured rapid yet accurate delivery of an anhydrous reagent). Vitamin A values were corrected for the blue color contribution of the carotene present in the sample.

Vitamin E was determined on the 4 ml aliquot of the petroleum ether extract by the method of Quarte and Harris,¹⁸ modified only in that smaller volumes of extract and reagents were used. The interference of vitamin A and carotinoids was eliminated by catalytic hydrogenation as described by Quarte and Biehler.¹

Standard curves for vitamin A, carotene and vitamin E were prepared and frequently checked during the progress of the assays.

Whole blood vitamin C was determined by our semimicro modification of the method of Roe and Luether.¹⁸ The final total color volume was 4 milliliters.

Free and total cholesterol were determined by the digitonin method of Sperry¹⁹ with minor modifications. The use of alcoholic solutions of digitonin as suggested by Sobel and Mayer²⁰ and the washing of precipitates by solutions forcibly ejected from a syringe and needle made the use of individual stirring rods unnecessary.

The lipid phosphorus fraction was obtained by evaporation of the alcohol ether filtrate extraction with petroleum ether and precipitation with acetone and magnesium chloride.²¹ Final phosphato determinations were made with the reagent described by Comori.² The factor of 26 was used for conversion to lipid phosphorus.

Many of the various analyses were conducted in duplicate with good agreement.

RESULTS

Since the data presented below represent the results of some 1600 determinations, space does not permit the tabulation of individual determinations. Table I gives the values of the various assays \pm their standard deviation. Significance of differences in the supplemented and unsupplemented groups is indicated by "t" values.

It is apparent that although the supplemented patients received daily an amount of vitamin A at least ten or twenty times that contained in the diet of

All colorimetric determinations were done with a Model 11 Coleman spectrophotometer. It is possible to use 4 ml volumes in the large cuvettes of this instrument without affecting the sensitivity. If the cuvette is raised by a suitable cut in the cuvette holder and the rim of the holder is masked to exclude the rounded portion of the cuvette and the unfilled portion of the cuvette from the path of the incident light.

To obtain reasonably stable Carr Price end points with the Model 11 instrument it is necessary to reduce the intensity of the incident light to a minimum value as recommended by Callwell and Parrell.²²

Pure tocopherol crystalline carotene (90 per cent 10 per cent) and a distilled vitamin A concentrate containing 0.500 I.U. per gram were kindly supplied by Distillation Product Inc., Rochester, N.Y.

N Number of patients assayed

M Mean of N observations \pm standard deviation which is equal to $\sqrt{\frac{\sum (v-M)^2}{n-1}}$

t, Fisher's χ^2 test of the significance of differences in practice it is equal to $\frac{D}{E_0}$ (difference of means) For numbers of samples between 25 and 30 a factor of 2 is assumed to be significant ($P < 0.05$)

*At thirty six months the Vitamin A given to supplemented patients was discontinued

the unsupplemented patients, the blood level of vitamin A in the supplemented group was less than three times that in the unsupplemented group. This difference, however, was maintained throughout a period of thirty six months of supplementation. In the six month period when supplementation was withdrawn, the blood level of vitamin A of the supplemented group fell to a value approximating that of the unsupplemented patients.

Plasma carotene and whole blood vitamin C seem to be entirely unaffected by the supplementation, and the minor fluctuations in these two substances seen in both groups, no doubt reflect seasonal variations in the dietary. The assays at twenty four and thirty six months were done in the fall and those at eighteen and forty two months in the spring.

The small but statistically significant increases in the vitamin E level of the blood of the supplemented patients have not been reported previously. That this increase was due to the supplementation is evidenced by the abrupt return to the control level when vitamin A was withdrawn.

The supplemented patients showed a significant increase in blood cholesterol and phospholipid. At twenty four months and thirty six months the supplemented group was 11 per cent and 22 per cent higher in total cholesterol and 105 per cent and 128 per cent higher in phospholipid than the control group. Since these increases in cholesterol occurred in both free and total cholesterol fractions, the F/T ratio remained normal. Although the increase in cholesterol was statistically significant at twenty four months the phospholipid values did not become significantly different until thirty six months. The decrease in plasma levels of both cholesterol and phospholipid of the supplemented patients after discontinuance of supplementation suggests a specific effect of the supplement upon the level of these lipid constituents.

DISCUSSION

Glover, Goodwin and Morton⁵ have investigated the relation of plasma vitamin A levels to those of liver stores in rats and point out that the blood level of vitamin A is proportional to the amount of free or alcohol form present in the liver and not to the total liver stores of the vitamin.⁶ They suggest that the free or alcohol form of the vitamin is the 'functional' form and that to supply body tissues with greater amounts of vitamin A there must be an increase in blood vitamin A alcohol. These workers found that an increase in post absorptive free vitamin A in the blood can be obtained only by massive dosing which by virtue of the alcohol ester equilibrium in the liver increases the blood vitamin A alcohol content. This fact appears to be related to the prolonged period of treatment necessary in certain skin diseases which has been reported.^{7, 28}

A 'sparing' or 'synergistic' action of vitamin I upon vitamin A and carotene has been reported by Hielman and co workers⁹ and Harris and associates³⁰ and this subject has been reviewed by Moore.³¹ That vitamin A has a similar effect on vitamin E is suggested by our data. Both these substances have been shown to have a similar protective effect on unsaturated fatty acids.³¹ It is possible that the increased blood level of vitamin I with vitamin A sup

plementation may be related to an antioxidative effect of vitamin A upon the oxidative destruction of vitamin E or to decreased utilization or to both

Under the conditions of our experiment, there appears to be a clearly significant increase in plasma cholesterol and phospholipid as a result of vitamin A supplementation. Whether these increases are a direct effect of vitamin A upon the oxidative, storage, or transport mechanisms of lipids is unknown. Chaher, Jeune, Simon, and Alaeoque³² and Wendt³³ suggested a relation of vitamin A to the thyroid gland. Recently, Sadhu and Biedy³¹ reported that doses of 30,000 units of vitamin A a day to rats decreased thyroid size and basal metabolism. From this work they postulate a direct relationship between vitamin A, thyroid, and thyrotropic hormone. Such a relationship might account for a lowered tissue oxidation of metabolites and thus lead to an increase in blood levels of lipids. It must be kept in mind, however, that doses of this order of magnitude are close to the toxic level for rats and far exceed the nontoxic amounts used in our study.

Although the cholesterol and phospholipid levels of the supplemented patients were significantly higher than those of the unsupplemented patients, it should be pointed out that the mean values are within normal range. The relation, moreover, between the several lipids is normal. Peters and Van Slyke³⁵ have charted ratios for both normal and abnormal amounts of cholesterol and phospholipid. Their lipid phosphorus cholesterol ratio charted against F/T cholesterol ratios defines the limits of normal variations of these lipids. Our figures, both for supplemented and unsupplemented patients, fall within their normal area number 5. This indicates that the hyperlipemia induced by 100,000 units of vitamin A daily lies within normal limits.

The effect of supplementation for periods greater than thirty-six months cannot yet be stated with any accuracy. Preliminary treatment of data obtained from patients in the private practice of one of us (J. V. S.) who were taking 100,000 units of vitamin A daily for 5 to 10 years, indicates plasma vitamin A, vitamin E and lipid levels indistinguishable from those of patients supplemented for three years.

As far as we know, the 100,000 units of vitamin A in the capsule used in this work was the only significant added substance in the dietary intake of the patients. The cholesterol and phospholipid and oil content of the capsule was only a small increment of the daily intake of these substances and the vitamin E content was approximately 3 per cent of the estimated human daily requirement.³⁶

SUMMARY

Thirty-six unsupplemented patients and thirty-six patients supplemented with 100,000 units of vitamin A daily for thirty-six months were studied. Blood assays at eighteen, twenty-four, and thirty-six months and a final assay at forty-two months, six months after supplementation was discontinued, are reported.

1. It was found that the mean plasma vitamin A level after thirty-six months of supplementation was 125 per cent higher than that of the unsupplemented patients. Six months after supplementation was discontinued, the mean levels, although still statistically higher than those of the controls, had fallen to half of their peak values.

2 No effect upon the carotene and vitamin C blood levels was observed

3 After eighteen, twenty four and thirty six months the vitamin E levels of the supplemented patients were 15.4, 22.5, and 25.7 per cent, respectively, higher than control levels

4 Both free and total plasma cholesterol levels of the supplemented patients were increased at twenty four and thirty six months to the extent of 13.8 and 20.8 per cent for free and 11.1 and 22.3 per cent for total cholesterol. F/T ratios, however, remained normal. Each of the increases seen in Vitamin E and cholesterol proved to be statistically significant

5 Although the phospholipid levels of the supplemented patients were 10.4 and 18.5 per cent higher than those of the controls at twenty four and thirty six months, respectively, only the thirty six month figure proved to be statistically significant

6 Assays made six months after high vitamin A supplementation was discontinued showed that the previously indicated elevations of vitamin E, cholesterol, and phospholipid had returned to levels not statistically different from the controls

A COMPARATIVE STUDY OF MICRO AND MACROELECTROPHORETIC ANALYSIS OF HUMAN AND RAT SERUM

PHILIP P. COHEN, M.D., AND FRANCES L. THOMPSON, B.S.
MADISON, WIS.

A DETAILED comparative study of electrophoretic analysis of protein solutions using a microcell (2 ml. capacity) and the standard macrocell (11 ml. capacity) has not been reported previously. Ross, Moore and Miller¹ published a study on human seminal plasma in which a microcell was used. They stated that the mobilities and character of the patterns obtained agreed exactly with those observed with the 11 ml. cell. Comparative data, however, were not reported.

Since the length of the channel of the microcell is only five ninths that of the macrocell, the time of electrophoresis becomes a limiting factor when proteins with relatively high mobilities, such as albumin, are being studied. Thus, in the case of serum, complete resolution of the components will be dependent in part upon the migration distance of the albumin component in the microcell. Aside from this, there is no theoretic basis for anticipating differences in electrophoretic analysis with the two cells. However, the fact that the two cells are different in design and manipulation would make a detailed comparative study desirable. The great value of having available a microcell for electrophoresis of small samples is obvious.

METHODS AND PROCEDURES

Use of the Microcell —

The microcell used in this study is a commercially available model and has the following dimensions: capacity, 2 ml., length of center section 5 cm., cross sectional area 0.30 centimeter. The cell and the microelectrode vessels are mounted in a special rack adapted for the micro assembly. The center section of the microcell is moved by a pair of sliding racks and pinions, as with the macroassembly.

Since the commercially available microcells are open on both sides a few modifications of the usual technique are necessary. In the first place, it is necessary to lower the water level of the bath to a point just below the top of the microcell. Since with the usual low temperature bath arrangement this will leave a portion of the cooling coil exposed it is necessary to lower the coil to a point where it is completely immersed at the lower water level. It is obvious that unless this is done the coil will ice and freeze the stirrer. It is desirable when lowering the coil to arrange for a pair of oppositely pitched puddles on the stirrer to aid in circulating water at the top and bottom of the coil. Special masks with slits adapted to the microcell dimensions must be used. The mask over the schlieren lens and the slit mask used in scanning are modelled after the macromasks. It was found convenient to solder a pair of piano wires across the inner surface of the slit mask toward the top and bottom to serve as reference lines.

From the Laboratory of Physiological Chemistry, University of Wisconsin Medical School.
Supported in part by a grant from the Wisconsin Alumni Research Foundation.

Received for publication Oct. 10, 1947.

Obtainable from either the Litt Manufacturing Co., New York, N. Y., or the Pyrocell Manufacturing Co., New York, N. Y.

It is possible to close off one side of the microcell by the use of a close fitting lucite plug inserted into the upper section. In this way the microcell can be used in much the same manner as the macrocell. If this is attempted the electrode is placed on the closed side and the other electrode is placed with a three way stopcock etc.

The microcell is set up in essentially the same manner as is the larger cell.² The electrode vessels are attached and filled with particular care to remove entrapped air bubbles from the small side arms. The cell carrier is placed in the thermostat, saturated salt solution is added to surround the electrodes, and the whole system is allowed to equilibrate. Before aligning the cell, it has been found necessary to remove the excess buffer from the bridge between the two channels of the top section. This is most readily effected by blotting with a piece of filter paper. Because of differences in the specific gravity of the protein and the buffer solutions on the two sides of the cell, it is advisable to equalize the hydrostatic pressure on the two sides by removing a small amount of buffer from the top section of the protein side before aligning the cell. This serves to prevent a rapid shift in the position of the boundaries once they are formed. As a convenient method for bringing the boundaries into view, one end of a piece of fine glass capillary is attached by means of rubber tubing to the compensating syringe and the drawn out end is inserted directly into the top section of the cell on the ascending (anode) side. The compensator gears are then reversed, whereupon a slow and regular withdrawal of fluid takes place.

Once the boundaries are in view, the starting position and base line pictures can be taken. Electrophoresis is then carried out in the usual manner except that the voltage is reduced so as to maintain approximately the same potential gradient of 5 to 6 volts per centimeter. Because of the smaller cross sectional area of the microcell, a current of 8 Ma was maintained throughout the run, rather than the 15 Ma used with the macrocell. Under these conditions the electrophoresis time for serum is limited to about ninety minutes because of the short length of the center channel of the microcell.

In all instances serum samples were diluted with two parts of buffer before dialysis.

RESULTS

In Table I are listed values obtained with ten different pathologic human sera using both the micro- and macrocell. As can be seen, the correlation co

Diagnosis of cases as follows: 1 nonlipoid histiocytosis (Letterer-Siwe's disease); 2 carcinoma of esophagus with metastases; 3 granulocytosis with terminal lobes pneumonia; 4 malignant mesothelioma of pelvis; 5 localized Hodgkin's disease with infiltration of lungs; 6 arteriosclerosis generalized; 7 myelogenous leucemia; 8 hypernephroma with metastases; 9 hypertensive and arteriosclerotic heart disease with multiple pulmonary emboli; 10 broncho pneumonia. Electrophoretic analyses of cases 1 to 9 have been previously reported.³

$$r = \text{Correlation coefficient} = \frac{\sum x_1 y_1}{\sqrt{\sum x_1^2 \sum y_1^2}} \text{ where } x_1 = \bar{x} - x$$

$$s_x = \text{Standard deviation (S.D.) } s = \sqrt{\frac{\sum x^2}{n}}$$

p = Probability of chance variation obtained by use of r values and a table of probabilities. p value of < 05 indicates the probability of chance variation of less than 5 in 100. p value of < 01 indicates chance variation of less than 1 in 100.

efficients are high in all instances except in the case of the beta globulin values. The known difficulty of accurately defining and measuring the beta globulin area on the descending side in all probability accounts for the less satisfactory but still significant correlation of these values.

In Table II are listed two sets of values taken from the same individual. The microdeterminations represent three different samples taken within a period of one month, the macrodeterminations represent triplicate determinations on a single sample taken from the same individual one year later. It is apparent that the range of variation within the two sets of determinations is of the same order in both the micro and the macro runs.

serum, they indicate that in a series of determinations using normal rat serum the percentage compositions will be comparable whether determined with the micro- or the macrocell

A comparison of mobility values obtained with the micro- and macrocell with rat and human serum is shown in Table IV. While the mean values are in reasonably close agreement, it is of interest that the standard deviations in the case of the rat serum macrodeterminations are considerably higher than those for the microdeterminations. In all probability a larger series of samples would not show this.

Fig 1—Comparison of macro- and microelectrophoretic patterns of normal human serum. Electrophoresis time: macro 150 minutes; micro 90 minutes. Protein concentration 2 Gm per 100 milliliters. Relative dimensions of patterns are maintained.

In Fig 1 tracings of a macro- and a microelectrophoretic pattern of normal human serum from the same individual are reproduced. It is apparent that resolution after 90 minutes with the microcell compares favorably with that of the macrocell, run for 150 minutes.

macro	6.1	0.32	5.4	0.37	4.3	0.35	2.9	0.20	1.7	0.31

In Fig. 2 tracings of a macro and a microelectrophoretic pattern of two different normal rat sera are shown. It is to be noted that while rat serum does not show the ready resolution seen with human serum the macro and micro patterns are quite comparable.

Fig. 2.—Comparison of macro and microelectrophoretic patterns of normal rat serum. Electrophoresis time: macro 180 minutes; micro 90 minutes. Protein concentration 2 Gm. per 100 milliliters. Relative dimensions of patterns are maintained.

DISCUSSION

The comparative data for macro and microelectrophoretic analyses of serum proteins reported here indicate that the values obtained by the two methods are in close agreement. In instances in which one is dealing with samples of serum of small volume the practical importance of the microcell is apparent. However, it is important to emphasize that a series of comparative determinations of the type reported here may be required in any study in which the two cells are to be used, particularly when quantitative differences of small magnitude are anticipated. It should also be pointed out that protein mixtures other than serum have not been extensively studied and therefore preliminary investigation of completeness of resolution of the component proteins must be established beforehand.

SUMMARY

1 Electrophoretic patterns of normal and pathologic human serum and normal rat serum have been compared using a micro- and a macroelectrophoresis cell. The mobilities and per cent composition of the components are in close agreement by the two methods.

2 Some technical aspects of the use of the microcell are presented and discussed.

STERNAL MARROW HELMOSIDERIN

A METHOD FOR THE DETERMINATION OF AVAILABLE IRON STORES IN MAN

CHARLES E. RATH, M.D.,* AND CLEMENT A. FINCH, M.D.†

BOSTON, MASS.

A KNOWLEDGE of the available iron stores is useful in the management of anemia. The extreme manifestations of iron lack such as koilonychia, glossitis, dysphagia, and microcytic hypochromic red cells are the result of a long existing deficiency. Iron excess is even more difficult to recognize than its lack, except in cases of hemochromatosis or severe hemosiderosis where there are pigmented deposits in the skin or in the urinary sediment. The majority of clinical problems in iron metabolism lie between these extremes, and in this group the examination of sternal marrow has proved to be a convenient and reliable index of iron deficiency or iron excess.

MATERIAL AND METHODS

One or more sternal punctures were performed on sixty-three individuals. This group included eleven normal subjects, sixteen patients with iron deficiency anemia, eleven with pernicious anemia, six with uremia, five with ulcerate or chronic infection, five with cirrhosis of the liver, three with lupus erythematosus, two with hemochromatosis, and four with hemosiderosis secondary to multiple transfusions. Only clear cut examples were selected for this report in which there was a careful history relevant to blood loss and iron intake by mouth or parenterally. Patients with iron deficiency anemia showed typical microcytosis and hypochromia which were associated with a low serum iron in the patients in whom the serum iron was determined. The diagnosis of pernicious anemia was confirmed by the characteristic cell indices and blood cytologic changes, megaloblastic sternal marrow, and a satisfactory reticulocyte response to intramuscular liver. Those with uremia presented the clinical picture of severe renal damage with a blood urea nitrogen in the neighborhood of 100 mg. per cent. Patients in the infectious group had a daily oral temperature of 100 F. and above for more than two weeks. All the patients with cirrhosis had obvious impairment of function tests and other stigmata of chronic liver disease. Both patients with hemochromatosis presented the typical hepatic lesions of that disease by biopsy and had a high serum iron with complete saturation of the iron binding protein characteristic of hemochromatosis.¹ The four patients with extensive hemosiderosis had had twenty-eight, eleven, fifty, and forty-nine transfusions respectively.

Sternal punctures were performed‡. After preliminary novocain infiltration a 2½ cm. No. 14 needle with a short bevel is introduced into the sternal marrow cavity in the midline at the level of the second interspace. The stylet is then withdrawn and 4 c.c. of marrow and blood are drawn into a 20 c.c. syringe containing 6 c.c. of 4 per cent sodium citrate. This mixture is then ejected into a large watch glass and cover slip films are made from marrow fragments picked up with a capillary pipette.

The preparations are examined microscopically both unstained and after staining with hydrochloric acid and ferroxyanide (Berlin blue stain)§. In the unstained preparations the hemosiderin appears as golden yellow granules under reduced illumination. In the stained preparation the granules take a blue stain. Not infrequently structures other

¶According to the technique employed by Dr. Joseph Ross.

§The stain was prepared as follows: 4 Gm. of potassium ferroxyanide were diluted to 20 c.c. with water. Concentrated hydrochloric acid was added until a white precipitate formed. This was filtered and the smears covered with the filtrate for thirty minutes.

than hemosiderin will stain, usually in proportion to the amount of iron present. These artifacts can be recognized with experience and by comparing the two types of preparation. In iron deficiency, pale yellow granules which do not take iron stain are sometimes seen. These may be analogous to the protein granules of hemosiderin remaining after removal of iron by extraction with 10 per cent hydrochloric acid.² The pale yellow color is probably due to adsorbed bilirubin. The smears were graded according to the amount of iron present.

2	Slight	6	Very heavy
3	Moderate		

RESULTS

In Fig 1, examples of these marrow preparations are demonstrated. Each marrow was graded independently by each of us and there was close agreement in most of the material examined. The independent ratings rarely varied more than one grade in either direction.

In the normal group the marrow iron was graded as 1 or 2 in every case except one which received a grade of 3 (Table I). All of the patients with

iron deficiency anemia showed a marrow iron of 0 or 1 (Table II). Of the eleven patients with pernicious anemia only one showed a marrow iron of less than 3, and five of the eleven showed a marrow iron of 4 or more (Table III). In the patients studied, the granules presented a somewhat characteristic appearance in that they were small, numerous and of uniform size (Fig 1, 3). In the patients with anemia the sternal marrow iron ranged from 0 to 4 plus (Table IV). The erythrotic patients showed a normal or increased iron in three of five patients (Table V). Five patients with infection showed an increase in the marrow iron (Table VI). Three patients with lupus erythematosus showed a heavy marrow iron deposition (Table VII). The heaviest iron deposition, grades 5 and 6, was seen in the patients with hemochromatosis and hemosiderosis (Tables VIII and IX).

COMMENT

Storage iron in man exists as ferritin and hemosiderin. The precise relationship between them is not clear. It would appear however that ferritin represents a labile or active form of iron storage and that hemosiderin is a less active form of iron storage present only when there are adequate ferritin stores.² The studies of Bogumil and Whipple have demonstrated that hemosiderin is mobilized for hemoglobin production when needed by the body.⁴ Of these two forms of iron storage hemosiderin is the only one morphologically identifiable. These yellow or brownish yellow granules are found throughout the reticuloendothelial system and macrophages of the body. The sternal marrow provides a readily accessible portion of the reticuloendothelial system for biopsy.

In this group of patients the sternal iron has been consistent with the alteration of iron storage characteristic of these diseases. In infection there was

an increase in hemosiderin above the amount normally seen. The progressive hemosiderosis in this condition appears to be due to an increased affinity of the tissues for iron. In pernicious anemia there is likewise an increase in tissue iron due in part at least to storage of red cell iron in the tissues. In hemochromatosis, sternal iron is increased as are other iron stores throughout the body. Multiple transfusions provide even heavier deposits of iron since the iron provided by the donated red cells is not excreted in appreciable amounts from the body. Patients with cirrhosis and nephritis have variable iron stores due to the variable bleeding in these diseases. Iron deficiency, in contrast to the normal controls and the other diseases described, shows an absence of iron staining granules. In this group of patients subsequent iron therapy was effective in alleviating the anemia.

It is to be expected that the balance of blood loss and iron absorption over a period of years will vary considerably from person to person, although this is remarkably well regulated by the absorptive mechanism.⁶ However, certain conditions will modify the stores to an extent which overshadows these normal variations. That a clear-cut differentiation of the anemia of infection from that of iron deficiency usually may be made is evident from comparing Table II and VI. Hemochromatosis also may be excluded in patients with cirrhosis if the marrow iron is not increased (Tables V and VIII).

A number of patients referred to us with mild anemias reputed to be iron refractory were shown by marrow puncture to have adequate or increased iron stores. Those anemias were felt to be due to other causes, that is, obscure infection or damaged bone marrow. In our experience, only patients with absent marrow iron will be benefited by iron therapy.

SUMMARY

A method of estimating tissue iron stores by sternal puncture has been described.

A group of sixty-three patients have been studied and the hemosiderin content of the marrow was found to parallel the anticipated iron storage in these diseases.

The presence or absence of iron in the marrow may be regarded as an index of the need for iron therapy in anemia.

OCCURRENCE OF TOXOPLASMA NEUTRALIZING ANTIBODIES IN VARIOUS DISEASE CONDITIONS

ISAAC RUCHMAN, PH D
CINCINNATI OHIO

THE toxoplasma neutralization test has been used extensively as an aid in the diagnosis and recognition of nonfatal and inapparent infection in man. With this procedure or the unequivocal demonstration of parasites in tissues either by animal inoculation or by histologic methods, it has been found that toxoplasmic infection can be responsible for many conditions such as (1) congenital encephalomyelitis, which becomes manifest either in utero or shortly after birth (2) acute encephalitis in children, (3) infection in adults resembling Rocky Mountain spotted fever, and (4) mild or inapparent infection. An investigation of the occurrence of toxoplasma neutralizing antibodies in the blood of certain selected individuals is the basis of this report.

The method for performing the neutralization test has been reported in detail by Sabin¹ and consists of the following procedure with minor modifications. A freshly prepared 10 per cent toxoplasma infected mouse brain suspension in saline is allowed to sediment spontaneously for one half hour. The supernatant fluid is drawn off and further dilutions of 1:50, 1:500 and 1:5,000 are made. Equal volumes of these dilutions (0.15 cc) are added to undiluted serum (or Tyrode's solution for the controls) giving final dilutions of 1:20, 1:100, 1:1,000, and 1:10,000. The mixtures are incubated at room temperature for approximately one half hour at which time 0.2 cc amounts are injected intracutaneously on the back of a rabbit. The lesions which develop are measured at the end of seven days. The inhibition of skin lesions by the test sera are compared with control lesions and the degree of neutralization determined. The criteria for interpretation of results are those advanced by Sabin.¹

Serum specimens were kept as fresh as possible and either used immediately or stored in dry ice until needed. They were obtained from individuals who along with other signs presented one or more of the following manifestations: hydrocephalus or microcephaly, cerebral calcification, chorioretinitis or other eye changes, and involvement of the central nervous system. Members of the immediate families were also examined for the presence of antibodies wherever indicated. Tests were also performed on patients with diseases of unknown etiology in order to determine a possible relationship to toxoplasmosis. Individuals suspected of having a congenitally acquired illness were also tested.

The results of the ninety tests performed with the sera from seventy-two individuals are listed in the following tables. Reported in Table I are positive results on seven patients, one month to five years of age, who presented evidence

From the Children's Hospital Research Foundation and the Department of Bacteriology and Pathology of Cincinnati College of Medicine.
Test performed between September 1944 and October 1946.
Received for publication September 10, 1947.

of having acquired the infection in utero, since they were either sick at birth or became sick shortly after birth. Six of the patients in this group had cerebral calcification, five had chorioretinitis or other signs of eye involvement, three had hydrocephalus, one had microcephaly, and six manifested convulsions or other signs of central nervous system involvement. Additional findings were a rash in two patients and splenomegaly in one patient. It is now apparent that cerebral calcification and central chorioretinitis are the important signs of congenital toxoplasmosis. One or the other or both were present in six of the patients. The seventh showed only microcephaly and mental retardation. In each instance tests of the mothers' sera showed toxoplasma neutralizing antibodies, further proof of the congenital inception of the disease. The father and an older sibling of one of the patients also developed antibodies. It is noteworthy that the serum from patient Bla,⁴ which was positive at the age of one year, still showed the presence of antibodies when tested more than five years

later. Inoculation of spinal fluid and blood from two of the patients (Kam and Lyk) into mice was without effect. However, toxoplasma were readily recovered from animals inoculated with ground suspensions of tissues obtained from patient Gri at autopsy. Positive tests on the sera of four other patients (7 to 62 years of age) are also reported in Table I. In these patients the onset of the illness could not be determined with certainty. Patient Kre, 7 years of age, showed unilateral chorioretinitis (type not determined) and psychomotor

disturbances. The mother was not available for testing. Patient Lyk, 9 years of age whose serum was positive, had had encephalitis for the previous six weeks. A retest several months later was again positive while the mother's serum was negative. Included in this series are two adults: one, a 32 year old fearful psychoneurotic patient with a questionable optic atrophy, and the other a 62 year old male who was said to have had encephalitis of about one week's duration from which he completely recovered. Two months previously he had been bitten by a cat that later died in convulsions. One cannot assume, however, that toxoplasma were the cause of these conditions because these patients might have acquired the antibody sometime in the past as a result of inapparent infection.

○ Did not neutralize M mother S sibling -- not available

† Patient too young to develop own antibodies

As recorded in Table II the sera of ten children with hydrocephalus (one month to three and one half years of age) were completely negative for toxoplasma neutralizing antibodies. In most instances the hydrocephalus resulted from developmental defects or trauma but in two patients only the hydrocephalus was associated with chorioretinitis. Patient Car had chorioretinitis in the macular region of both eyes and hydrocephalus at the age of 1 month. It should be pointed out, however, that the neutralization test may be negative in a newly born infant and positive when the child is several months old. Thus it is of greater importance to test the mother's blood as early as possible after the birth of the baby, and the child's blood several months later. Unfortunately in this case neither the child nor the mother was available for subsequent tests. Patient Lit, with a possible onset at one year of age developed hydrocephalus convulsions and chorioretinitis whose type and distribution was not determined. In this instance the sera of the child and the mother were negative. It is worth noting that in the series of children without antibodies the mothers' sera were also found to be negative. The instances in which the sera of both mother and

child are positive therefore assume greater significance as serologic evidence for a diagnosis of congenital toxoplasmosis

Cerebral calcification in the absence of toxoplasma neutralizing antibodies was encountered four times (Table III). In two of the patients (Fle and Ste) the calcification was associated with developmental defects. However, toxoplasmosis could not be excluded with certainty in two (Bel and Nei), one patient in particular (Bel) having manifestations compatible with a diagnosis of toxoplasmic infection. The sera from the mother and child were sent through the regular mail during the hot summer months without any precautions for preserving the heat-labile toxoplasma antibody. Even so, they were not completely negative and it is highly probable that antibodies might have been demonstrated in a fresh specimen. Further specimens were not obtainable. Patient Nei also gave a history compatible with a diagnosis of toxoplasmosis, but repeated tests many months apart failed to reveal neutralizing antibodies in either the mother or the child. The absence of neutralizing antibodies in a child showing the clinical signs of congenital toxoplasmosis has been reported.¹ Both the mother and child failed to show toxoplasma neutralizing antibodies on repeated tests but regularly showed the presence of complement-fixing antibodies. Again in this group the mothers as well as the offspring lacked the neutralizing antibodies.

TABLE III PATIENTS WITH CEREBRAL CALCIFICATION WHOSE SERA FAILED TO NEUTRALIZE TOXOPLASMA

*⓪ Did not neutralize. M, mother.

†Serum specimens were in the mail for several days during the summer months. Results of the neutralization test were equivocal.

Negative results were obtained with the blood of six patients, 2 months to 27 years of age with retinal lesions but without signs of hydrocephalus or cerebral calcification (Table IV). In addition to other symptoms, two members of the group, age 2 and 5 months, respectively, developed convulsions. The 5-month-old child had central chorioiditis and nystagmus as well. Serum tests of the mothers of these children were likewise negative for toxoplasma antibodies. The remaining four patients were of sufficient age to develop antibodies but, since none were found, no attempt was made to examine the mothers' blood. The type and distribution of lesions in these individuals as well as the possible

TABLE IV PATIENTS WITH EYE CHANGES WHOSE SERA FAILED TO NEUTRALIZE TOXOPLASMA

INCEPTION	PATIENT	AGE	FINDINGS	RESULTS OF NEUTRALIZATION TESTS WITH SERA FROM IMMEDIATE FAMILY*
Congenital	Mol	2 mo	Eyes closed, slight retinal changes convulsions	(M)
	Ans	5 mo	Bilateral macular chorioretinitis, nystagmus convulsions	(M)
	Hil	3½ yr	Failure to develop since birth chorioretinitis (2 years later)	--
Probably congenital	Gai	2 yr	Bilateral chorioretinitis (diffuse pigmented)	--
Acquired	Glo†	19 yr	Active bilateral macular chorioretinitis	-
	Rom	27 yr	Bilateral chorioretinitis (hemorrhagic) in last year	-

*O. Did not neutralize M mother — not available

†Equivalent on repeated tests

onset are listed in Table IV. The chorioretinitis was first noted about two years after birth in patient Hil. In the adults, Glo and Rom, the chorioretinitis was active and had developed within the past year.

The determination of neutralizing antibodies was extended to include disease conditions in which a definite etiology could not be established. When individuals with signs of hydrocephalus, cerebral calcification and chorioretinitis had been eliminated there was still a large group (ages 7 months to 7½ years) that showed negative neutralization tests. In many instances (especially in children with congenitally acquired diseases) the tests were performed to exclude the possibility of toxoplasmosis. The primary diagnosis or chief findings are listed in Table V. In this group three patients had prolonged encephalitis, six had encephalopathies of obscure etiology, three were believed to have Hodgkin's disease, one was a patient with eosinophilia and one with hepatosplenomegaly; there was also an individual who had been exposed to toxoplasma in the laboratory for many years.

TABLE V CONDITIONS WHICH FAILED TO PRODUCE TOXOPLASMA NEUTRALIZING ANTIBODIES

PATIENT	AGE	DIAGNOSIS
Dho	7 mo	Lamellar demyelinating sclerosis
Aho	18 mo	Lamellar demyelinating sclerosis
Vo	2 yr	Congenital bone abnormality, mental retardation
But	2½ yr	Encephalitis last 6 weeks (convulsions, ataxia, pasticity, pleocytosis)
Wal	5 yr	Right cerebral atrophy, epilepsy, convulsion, pasticity
Smi	8 yr	Eosinophilia
Fem	8 yr	Prolonged encephalitis, cortical atrophy, mental retardation
Bnl	14 yr	Brain abscess
Dav	15 yr	Acute encephalitis (toxoplasma isolated from animals inoculated with C S F) patient tested seven years later
Fla	18 yr	Hodgkin's disease
Tro	30 yr	Hodgkin's disease
Lap	38 yr	Hodgkin's disease
Ruc	37 yr	Laboratory exposure for many years
Sak	40 yr	Epileptic seizures, abortions
Hes	74 yr	Hepatosplenomegaly, emphysema of gall bladder

Ca. reported by Sabin*

DISCUSSION

With the aid of quantitative methods, Sabin and Ohtsky⁶ were able to demonstrate the development of toxoplasma neutralizing antibodies in experimentally infected monkeys. Later, utilizing the same method, Sabin⁵ was able to show the presence of such antibodies in a human patient with toxoplasmosis, and this was soon corroborated by Cowen, Wolf, and Page.⁷ The latter were able to show not only that antibodies were present in the young patients but in some of the mothers as well, thus giving additional evidence for the belief that the disease was congenitally acquired by those patients. Certain discrepancies regarding the presence of neutralizing antibodies were explained when Sabin and Ruchman⁸ discovered the extreme lability of the antibody and the ease with which it disappeared from stored serum unless proper precautions were taken for its preservation. Sera kept frozen in dry ice or lyophilized were found to retain their antibody content for long periods of time. With due regard for the instability of the antibody, it was noted that neutralizing substances appeared in the blood stream of monkeys within two weeks after infection and persisted for over a year, which was the longest interval tested. It was also observed that the presence of antibody was not associated with the persistence of parasites in the tissues of the monkeys. Having ascertained that the neutralization test yielded reproducible results, Sabin¹ extended the work to include sera obtained from human beings. It was found that neutralizing antibodies were almost regularly present in infants and children showing psychomotor disturbances with or without hydrocephalus or microcephaly only when these were associated with cerebral calcification or chorioretinitis or both. Corroboration was obtained of the presence of antibodies in the mothers of affected children. Occasionally other members of the immediate family were found to be positive. In a high proportion of patients examined, neutralizing antibodies were found in patients with obscure encephalopathies, in mothers who gave birth to anencephalic, microcephalic, or hydrocephalic infants, and in older children with chorioretinitis as well as some of their mothers. The latter were made the basis of a separate report by Vail and co-workers.⁹ Callahan¹⁰ studied the sera of one hundred apparently well adults and found that only 2 per cent were able to neutralize the effects of toxoplasma. Heidelman¹¹ corroborated the finding of a high incidence of positive sera in patients with congenital chorioretinitis as well as in many of their mothers. The incidence was approximately 10 per cent in cases of acquired chorioretinitis and much less in patients with acquired anterior uveitis. A case diagnosed clinically as toxoplasmic in origin was used by Adams and associates¹² to study the sera obtained from members of the immediate family. They were able to show the presence of antibodies in the patient, the mother and nine of ten siblings. Finally, Johnson¹³ corroborated the finding of a high incidence of positive sera among patients with active or inactive central chorioretinitis, especially when cerebral calcification was also present. Among the sera of twenty-eight patients (15 to 50 years of age) with macular chorioretinitis alone, a total of 16, or 57 per cent, was positive. The sera from four individuals (3 to 5 years of age at first examination) who had cerebral calcification in addition to the chorioretinitis were positive. Again the

blood of the mothers (two of two tested) and of some of the siblings (eight of ten tested) of such patients was positive

The results reported in this series of toxoplasma neutralization tests corroborate the general finding of positive sera among patients with hydrocephalus or microcephaly and psychomotor disturbances when these are associated with chorioretinitis, particularly in the macular region of the eye, and with cerebral calcification. The high incidence of positive antibody tests in the mothers of these patients substantiates the evidence that the infection was acquired in utero. In at least one instance however the blood of a child with encephalitis was positive while the mother's blood was negative, indicating that the infection was probably acquired postnatally. It is not known to what extent the presence of antibodies means past infection. Indeed rough estimates place the incidence of neutralization from 2 per cent to about 10 per cent in different regions.¹⁻¹⁰⁻¹¹ Of greater importance is the constant association of a certain syndrome with the presence of neutralizing antibodies. In this case the problem becomes one of statistical study. Such studies have already demonstrated the close association between positive sera in young children presenting the cardinal signs of congenital toxoplasmosis on the one hand and the presence of antibodies in the mothers' blood on the other. Occasionally other members of the immediate family have had circulating antibodies against toxoplasma giving evidence to the belief that the infant acquired the infection in utero at a time when the infection was widespread among some members of the family.

Although no exact figures are available it would appear that antibodies once attained as a result of specific infection persist for long periods of time perhaps indefinitely. The longest period of examination was until about five years after diagnosis at which time the serum neutralized to the same extent as before. Numerous lesser intervals have revealed that the antibodies were still present in the blood stream. For example among the ninety tests performed on seventy two individuals, some repeat examinations with freshly drawn serum samples were included. The specimens were obtained anywhere from two weeks to twenty months after the initial bleeding tests were performed. Among the twenty two individuals with positive sera nine were retested of which eight remained positive and one became equivocal. Among the fifty negatives five were retested and all remained negative. Seven equivocal individuals were found and of these, four were reexamined at a later date. One remained doubtful two became negative and one turned positive. This last occurred in an infant suspected of toxoplasmosis whose test was equivocal at one month of age but became strongly positive at three months of age. This observation has been pointed out by Sabin⁴ and to a certain extent explains the negative and equivocal results obtained by others in an occasional infant with toxoplasmosis. It does not explain the observation by Heidelman¹¹ of individuals who neutralized and subsequently lost their antibodies. A suggested explanation is that the sera originally were actually equivocal, since we have recorded only one instance in which a positive individual eventually became negative. Even this individual was originally on the borderline of positive and later became

equivocal We thus far have not seen a strongly positive serum that later became completely negative

Negative tests were obtained in many of the disease conditions and the small selection reported here emphasizes the need of tests on additional diseases of obscure etiology to rule out the possibility of toxoplasmosis Such tests¹ have already excluded the possibility of toxoplasmic infection in patients with hydrocephalus, microcephaly, psychomotor retardation, or convulsions not associated with cerebral calcification or chorioretinitis or both All of the sera from ten patients with hydrocephalus or microcephaly in the absence of cerebral calcification or chorioretinitis were negative for neutralizing antibody These, together with the sera from eight of nine patients reported here, make a total of eighteen of nineteen patients tested that failed to show antibodies when neither cerebral calcification nor chorioretinitis was present

SUMMARY

The toxoplasma neutralization test performed in rabbits was used to determine the presence of antibodies in various disease conditions Of the sera obtained from seventy-two selected individuals, twenty were positive, forty-eight were negative, and four were equivocal Corroboration was obtained of the high incidence of the positive sera among children showing signs of congenitally acquired toxoplasmosis, namely, convulsions or other signs of central nervous system involvement and hydrocephalus or microcephalus when these were associated with cerebral calcification or chorioretinitis or both Antibodies were regularly present in the blood of the mothers of such patients Antibodies were also found in a child with prolonged encephalitis and in two adults with mental disturbances The toxoplasma neutralizing antibodies persist in the blood stream for at least five years which was the longest interval tested Many conditions of obscure etiology failed to show the presence of toxoplasma antibodies

Gratitude is expressed to Dr A B Sabin, Cincinnati, for channeling many of the requests to the author This investigation was made possible through the kind cooperation of the following physicians who furnished the specimens and histories Dr R F Birge, Des Moines, Iowa, Dr Beulah Cushman, Chicago, Ill, Dr Mariana Gardner, Denver, Colo, Dr Clifton Govan, Jr, Baltimore, Md, Dr Heiman Hoster, Columbus, Ohio, Dr A B Johnson, Cleveland, Ohio, Dr Thomas B Leberer, Baltimore, Md, Dr M C Miller, Pittsburgh, Pa, Dr Waldo E Nelson, Philadelphia, Pa, Dr A B Schwartz, Milwaukee, Wis, Dr Gregory Schwartzman, New York, N Y, and Dr Robert Wood, New York, N Y This opportunity is taken also to express gratitude to the numerous staff members and residents of the Children's Hospital, the Cincinnati General Hospital, and the Jewish Hospital, particularly to Dr Frank Nantz, Dr Joseph Ghory, Dr Josef Warkany, Dr Edgar Lotspeich and Dr William McGowan for their kind cooperation

LABORATORY METHODS

A COLORIMETRIC DETERMINATION OF CARONAMIDE

CARL ZIEGLER, B A , AND JAMES M SPRAGUE, PH D
PHILADELPHIA, PA

THE evaluation of a large number of substances of various chemical types for their property of inhibiting the renal elimination of penicillin has led to the selection of 4'-carboxy-phenylmethanesulfonamide (caronamide) for detailed study^{1, 2} The extensive pharmacological and clinical evaluation of such an agent requires a method for the quantitative determination of the substance in tissues and in body fluids The convenience and acceptability of the colorimetric method for the quantitative determination of sulfanilamide derivatives^{3, 4} led to attempts to adapt this method for the determination of caronamide Since caronamide (I) is a derivative of p-aminobenzoic acid, a cleavage to yield p-aminobenzoic acid (II) would permit the application of the diazotization method to this compound This general colorimetric procedure has been employed for the determination of p-aminobenzoic acid and its derivatives in biologic material^{5, 6}

Caronamide proved to be resistant to hydrolytic cleavage except under drastic conditions that resulted in the destruction of the p-aminobenzoic acid also However, it was found that the action of a powdered nickel-aluminum alloy (Raney catalyst alloy⁷) in alkaline solution gave complete and smooth cleavage In this method the reaction of the aluminum in the alloy with the sodium hydroxide results in a vigorous evolution of hydrogen The hydrogen, in contact with the nickel from the alloy, causes hydrogenolysis of the caronamide with the liberation of p-aminobenzoic acid which then may be determined by the established procedures

A description of the procedures for the determination of caronamide in urine, in plasma, and in blood is presented in this communication The application of this method to other compounds will be reported later

In the procedures for plasma and blood, 90 per cent alcohol proved to be a satisfactory protein precipitant Acid precipitants such as trichloroacetic acid or p-toluenesulfonic acid were not satisfactory because of the low solubility of caronamide in acid media and because of the large volume obtained when the

*Central Scientific Company, Chicago, Ill.

acid filtrate was neutralized and then made sufficiently alkaline for treatment with the alloy. In the case of plasma it is not essential that the protein be precipitated. In the alternative procedure the plasma in alkaline solution is treated directly with the alloy.

REAGENTS

- Sodium hydroxide solution, approximately 5 per cent
- Raney catalyst alloy
- Hydrochloric acid, approximately 6 N, the concentrated acid diluted with an equal volume of water
- n-Octyl alcohol, to prevent forming with alloy treatment
- Sodium nitrite, 0.2 per cent solution freshly prepared
- Ammonium sulfamate 2 per cent solution
- N (1 Naphthyl) ethylenediamine dihydrochloride, 0.1 per cent solution freshly prepared
- Ethanol, 90 per cent

PROCEDURES

For the determination of the p-aminobenzoic acid following the alloy treatment, a slight modification of the procedure described by Eckert¹ is used. N (1 Naphthyl) ethylenediamine is employed as the coupling agent. A Klett Summer on photoelectric colorimeter with a No. 54 green filter was used to read color intensities.^{2, 3}

I Determination in Urine—Two milliliters of the urine sample are diluted accurately to 10 ml with water.* One milliliter of this solution is added to 10 ml of 5 per cent sodium hydroxide solution in a 125 ml flask or a large test tube. Two drops of n-octyl alcohol are added and then 0.5 Gm of the Raney catalyst alloy†. The vessel is swirled gently to mix the contents. When the vigorous reaction has subsided, the mixture is heated on a steam bath or in a boiling water bath for twenty minutes. The mixture is cooled and the residual nickel allowed to settle. The aqueous portion is decanted from the nickel and the nickel is washed by decantation four times with distilled water. The aqueous solution and the washings are combined and diluted to 100 milliliters. Instead of washing by decantation the residual alloy may be separated by filtration or centrifugation‡ and the solution made up to 100 milliliters. Ten milliliters of the alkaline solution are added to 4 ml of 6 N hydrochloric acid§ with constant agitation and the acid solution is diluted to 50 milliliters.

To 10 ml of the acidified solution 1 ml of 0.2 per cent sodium nitrite solution is added. The solution is mixed well and allowed to stand for five minutes. One milliliter of 2 per cent ammonium sulfamate solution is added, the solution is mixed and allowed to stand for three minutes. Finally, 1 ml of the 0.1 per cent solution of N (1 naphthyl) ethylenediamine dihydrochloride is added and the solution is mixed. After thirty minutes the intensity of the color is read. Distilled water is used as a blank. The concentration of caronamide in the original urine sample is obtained by reference to a standard curve constructed by plotting colorimeter readings obtained when a series of standard solutions of drug is carried through the foregoing procedure.

II Determination in Plasma—A 2 ml sample of plasma is diluted accurately to 20 ml with 90 per cent alcohol and the suspension is thoroughly mixed. After standing for

*This primary dilution is desirable to minimize foaming during the alloy treatment and to reduce the concentration of caronamide.

†The alloy may be measured conveniently in a small measuring spoon that is shaped to hold approximately 0.5 gram.

‡Caution. The residual nickel must not be allowed to dry, since it is pyrophoric. It should be washed down the drain immediately with a large quantity of water.

§The alkaline solution must be added to the acid. If the addition is in the reverse order a precipitate forms which dissolves rapidly in the excess acid only when the mixture is warmed.

ten minutes the mixture is filtered through coarse paper and 10 ml of the filtrate are added to 10 ml of 5 per cent sodium hydroxide solution. Two drops of n octyl alcohol are added, followed by 0.5 Gm of the Raney alloy *. When the first vigorous reaction subsides, the mixture is heated on a steam bath or in a boiling water bath for thirty minutes. The alcohol is allowed to escape during this treatment. The mixture then is cooled, diluted to 100 ml, and filtered †. Ten milliliters of the filtrate are added to 1 ml of 6 N hydrochloric acid ‡. After the addition of 1 ml of 0.2 per cent sodium nitrite, the solution is mixed well and allowed to stand for five minutes. One milliliter of 2 per cent ammonium sulfamate is added. After three minutes, 1 ml of 0.1 per cent N (1 naphthyl) ethylenediamine dihydrochloride solution is added and the color is allowed to develop for thirty minutes. The color intensity is read, using distilled water as the blank.

The concentrations of caronamide are calculated by reference to a standard curve prepared by plotting colorimeter readings obtained by using this procedure on samples of plasma containing known quantities of the drug.

III Alternative Determination in Plasma—A 1 ml sample of plasma is diluted with 10 ml of 5 per cent sodium hydroxide solution. To this are added two drops of n octyl alcohol and 0.5 Gm of Raney alloy. When the first vigorous reaction has subsided, the reaction mixture is heated on the steam bath for thirty minutes. The mixture then is cooled, diluted to 100 ml, and filtered †.

A 10 ml aliquot of the filtrate is added to 1 ml of 6 N hydrochloric acid‡, after which 1 ml of the 0.2 per cent sodium nitrite solution is added. This is mixed well and allowed to stand for five minutes. One milliliter of 2 per cent ammonium sulfamate is added. After the solution has stood for three minutes, 1 ml of 0.1 per cent N (1 naphthyl) ethylenediamine dihydrochloride solution is added and the color is allowed to develop for thirty minutes. Intensity of color is read with the colorimeter. In order to correct for a slight turbidity that appears with some plasma specimens, a blank is prepared from a second 10 ml sample of the alkaline filtrate from the alloy treatment by omitting the sodium nitrite.

Concentrations of caronamide are calculated from a standard curve prepared by plotting colorimeter readings obtained by using the foregoing procedure on samples of plasma containing known quantities of drug.

IV Determination in Blood—A 2 ml sample of blood is added to 2 ml of water and the mixture is allowed to stand for ten minutes in order to allow hemolysis of the cells. This mixture is diluted accurately to 20 ml with 90 per cent alcohol. The suspension is mixed thoroughly, allowed to stand for ten minutes, and filtered. Ten milliliters of the filtrate are carried through the alloy treatment as described in II. A standard curve is constructed from values obtained with blood to which known amounts of the drug have been added.

Results With Standard Solutions—Solutions containing known amounts of p-aminobenzoic acid in water, in urine, in plasma, and in blood were prepared and run through the alloy treatment according to these procedures. The amounts of p-aminobenzoic acid recovered were calculated by reference to a plot of the colorimeter readings that were obtained on standard aqueous solutions not subjected to the alloy treatment. The results, which are tabulated in Table I, show that recoveries generally were 80 to 90 per cent. Therefore, 10 to 20 per cent of the p-aminobenzoic acid is lost during the alloy treatment. However, for each procedure the recoveries are fairly constant and reproducible.

Similarly, solutions containing known amounts of caronamide were subjected to these procedures and the recoveries of p-aminobenzoic acid were cal-

culated. Again the recoveries were generally between 80 and 90 per cent and were constant and reproducible for each procedure. Since the recoveries were essentially the same after the alkali treatment of either p aminobenzoic acid or caronamide it appears that the caronamide is split quantitatively but that an average of 15 per cent of the liberated p aminobenzoic acid either is destroyed during the treatment or is lost, possibly by adsorption on the finely divided nickel.

IV	20	9.4	7.8	83
IV	10	4.7	4.0	85

From these data it is evident that standard reference curves for use in routine determinations may be constructed from the colorimeter readings obtained when urine, plasma, or blood containing known amounts of caronamide are run through the appropriate procedure. From Table I and Table II it will be noted that procedure III, which is run on plasma without removal of protein, gives lower recoveries than does procedure II. Nevertheless, this procedure has proved to be useful in the analyses of a large number of routine specimens where extreme accuracy was not required.

For the best results the acid solutions used for the diazotization and coupling in these procedures should correspond to a caronamide concentration of between 0.15 and 0.4 mg per 100 ml, or approximately 0.075 to 0.2 mg per 100 ml of p-aminobenzoic acid. At these concentrations the scale readings of the colorimeter lie between 100 and 300.

With the dilutions employed in these procedures (1:2,500 for urine, and 1:100 for plasma and blood), caronamide concentrations in urine from 200 to 1,000 mg per 100 ml, and in plasma or blood from 5 to 50 mg per 100 ml, can be determined satisfactorily.

SUMMARY

A procedure for the colorimetric assay of caronamide is described. Treatment in aqueous alkali with nickel-aluminum alloy quantitatively liberates p-aminobenzoic acid which then is determined by established procedures.

A COMPENSATING PLETHYSMOKYMOGRAPH FOR MEASURING BLOOD FLOW IN HUMAN EXTREMITIES*

MAXWELL R BERRY M D,† EDWARD J BALDES PH D,‡
HIRAM E ESSEN, PH D,§ AND KHALIL G WAKIM M D PH D ||
ROCHESTER MINN

ACCURATE measurement of blood flow through the extremities of human beings has proved to be a fairly difficult problem. That plethysmographic methods are not completely satisfactory is attested by the fact that for the past thirty years new improvements of the original plethysmograph invented by Biot¹ and Russell² have been presented frequently. The skepticism of Pezzah³ concerning the value of this method for measuring blood flow has frequently proved to be justified although the plethysmograph has yielded a large volume of valuable physiologic information of qualitative if not quantitative significance. Unfortunately, however, most of the physical and physiologic principles on which the method is based have never been adequately analyzed. In fact, it has been demonstrated in only one organ⁴ (the kidney) that blood flow is measured by the plethysmographic method. Landowne and Katz⁵ have presented an admirable critique of the plethysmographic method of measuring blood flow in human beings.

PRINCIPLE OF PLETHYSMOKYMOGRAPHY

The term plethysmography is derived from Greek and literally means "the recording of the curve of filling." An organ or a portion of an extremity is sealed in a leakproof plethysmograph. A sphygmomanometer cuff connected to a pressure reservoir is placed about the extremity of the subject just proximal to the plethysmograph. This cuff is called the collecting cuff and its function is to produce occlusion of the veins. Sudden inflation of the collecting cuff to a pressure below diastolic blood pressure yet above venous pressure, traps incoming arterial blood within the portion of the extremity distal to the collecting cuff and thereby causes engorgement and increase in volume of the portion of the extremity which lies inside the plethysmograph. Connected by tubing to the inside of the plethysmograph is a recording device which is activated by a change of pressure within the plethysmograph. This change of pressure within the plethysmograph and recorder is induced by a change in volume of the enclosed portion of an extremity. The recorder may trace on a smoked drum or reflect a beam of light to record on moving photosensitive paper. The latter method is called the optical system of recording and is the more satisfactory of the two.

when sensitivity is essential. The rate of increase in volume of the portion of the extremity enclosed in the plethysmograph is measured by the extension of the recorder and a timing device. The increase in volume per unit of time, so obtained, is assumed to be an indication of actual blood flow to the portion of the extremity enclosed in the plethysmograph. The record obtained is called a "flow curve." Fig. 1 shows several types of flow curves which were obtained in this study.

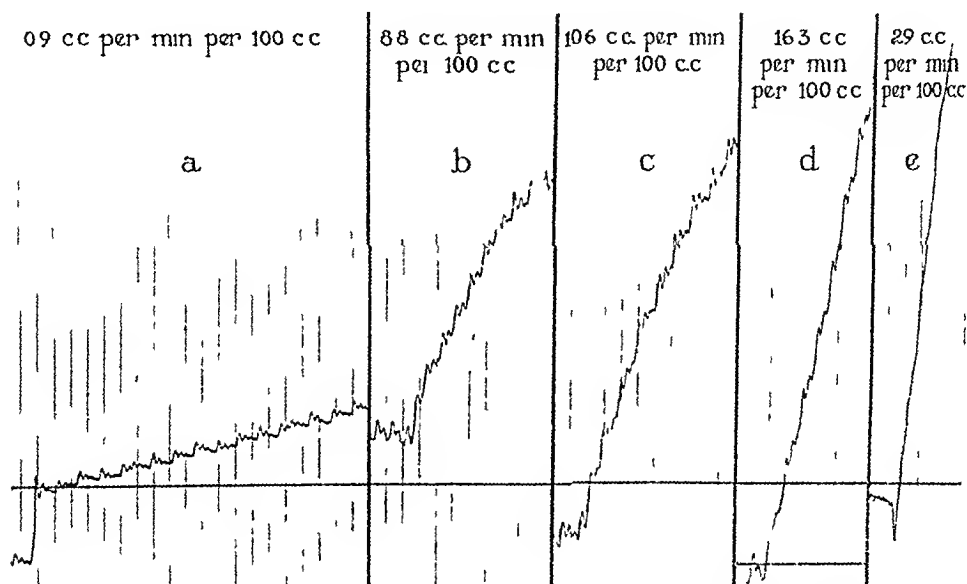

Fig. 1—Typical blood flow curves obtained from the arms of human beings by the plethysmographic method. Each record was taken on a different subject. Calculated volume flow for each curve is given at the top of the respective tracing.

The purpose of this communication is to describe a compensating plethysmographic method which we have developed. After careful analysis and appraisal of this and various other methods we have reached the conclusion that this compensating plethysmograph most nearly satisfies the criteria for accurate determination of blood flow in human extremities. The following are the main requirements which we consider essential for the accurate determination of blood flow through human extremities by the plethysmographic method.

- 1 Accurate measurement of pulsating changes in volume per second
- 2 Approximately normal environmental conditions
- 3 Complete and sudden arrest of the return of venous blood from the extremity without obstruction of the flow of arterial blood into the extremity
- 4 Elimination of or compensation for mechanical errors due to
 - (a) Displacement of fluid and tissue from beneath the collecting cuff into the plethysmograph during inflation of the collecting cuff
 - (b) Respiratory and other motions of the extremity
 - (c) Differences in calibration of the recording device due to the differences in the volume of various extremities

- (d) Changes in environmental temperature and pressure
- (e) Leaks in the apparatus
- (f) Slight variations in camera speed

Air was preferred to water as an environmental medium inside the plethysmograph for the following reasons

- 1 Water constitutes an abnormal environmental medium
- 2 The inertia of water might tend to slow down rapid changes in volume of an extremity
- 3 External water pressure may prevent increases in volume of the venous system
- 4 We desired a method of plethysmography which would be applicable to the leg and foot as well as to the arm and hand. With water as an environmental medium, the patient's knee must be at a higher level than the foot in order to prevent leakage of water about the point where the plethysmograph is sealed to the patient's extremity. If the patient's foot is at a lower level than his knee, venous pressure and the external pressure of the surrounding water are greater in the foot than in the leg and arterial blood should flow into the leg more easily than into the foot.

Fig. 1.—The arm plethysmograph with the arm prepared for insertion into the plethysmograph. *a* Open end of the plethysmograph. *b* Braided ring for clamping the occluding diaphragm to the open end of the plethysmograph (this is passed over the diaphragm before clamping). *c* Metal straps for swiveling the plethysmograph from above. *d* Plate glass window resting on rubber gasket. *e* Ring clamp holding the window in place. *f* Inlet for callibrator. *g* Outlet for a Marey tambour. *h* Outlet for wide bore tubing leading to the compensating spirometer recorder. *j* Outlet to the recorder for a finger plethysmograph. *k* Inlet for perfusing the plethysmograph when calibrating. *l* Inlet for inflation of the wrist cuff. *m* Rubber cellulose diaphragm. *n* Collecting cuff. *o* Wrist cuff.

DESCRIPTION OF APPARATUS*

Plethysmograph (Fig. 2).—A copper cylinder 18 inches (45.7 cm) long and 6 inches (15.2 cm) in diameter is closed at one end and open at the other. In the side of the cylinder is a rectangular opening 4 by 8 inches (10.2 by 20.3 cm) in diameter. A plate glass window held in place by a strong spring clamp

* We are indebted to Mr. A. N. Fort for his technical assistance.

Fig 3—Leg plethysmograph showing the various stages in the preparation of the leg for making an airtight seal around the leg when inserted into the plethysmograph without interfering with the circulation. The various outlets corresponding to those of the arm plethysmograph are located on the medial surfaces. *a* Constituent parts of leg plethysmograph. *b* plethysmograph applied to legs and made airtight without interference with circulation.

rests on a sponge rubber gasket which occludes the juncture between the edge of the rectangular window and the plate glass. When the plethysmograph is horizontal, the window is on the upper side and permits visualization of the limb. On the right side of the plethysmograph is a round opening large enough to convey the lead wires of electric thermocouples for determination of skin temperatures. Outlets for a Marey tambour and a calibrator are placed at the top of the distal end of the plethysmograph. On the side of the plethysmograph is a

connection for inflating a wrist cuff. On the distal end is an outlet for a recorder connected to a finger plethysmograph and another outlet for a recorder connected to the arm plethysmograph. The instrument is suspended and swung by means of a rope from a point above and moves freely from side to side or back and forth with respiratory and other involuntary motions of the extremities. The plethysmograph is rendered airtight by means of a thick, stiff sponge rubber diaphragm called the occluding diaphragm which is clamped over the open end of the plethysmograph by a heavy brass ring.

Plethysmographs for the lower extremities were made of cast aluminum as shown in Fig. 3. The major principle of their operation is the same as for the arm plethysmographs described previously. The plethysmographs were painted flat black in order to facilitate heat transfer and prevent abnormal variations of temperature.

Blank Plethysmograph—The blank plethysmograph is a replica of the aforementioned plethysmograph and is used in conjunction with compensating spirometers (see next section) to eliminate the errors induced in the estimation of blood flow by changes in the environment in temperature and pressure.

Compensating Spirometers (Fig. 4)—The recording device which we have named a compensating spirometer, is made up of two spirometers identical in capacity and form. Each spirometer is made of thin sheet brass in the shape of a hollow, truncated wedge. One of the broad sides of the wedge is omitted thus forming an inverted cup when the wedge is placed with the open side down. Each spirometer rotates about an axle mounted on ball bearings. The axles of the two spirometers lie in the same axis. Each spirometer floats on kerosene or "finol" contained in a square metal pan. A metal pipe pierces the bottom of the pan passes up through the contained kerosene and opens into the air pocket in the spirometer. Wide bore rubber or plastic tubing connects one spirometer to the plethysmograph and the other to the blank plethysmograph. In this way the enclosed space between the top of each spirometer and the surface of the kerosene is in communication with the respective plethysmograph. As the intraplethysmographic volume increases the spirometer rises as the volume decreases it falls. The spirometer pans are mounted side by side and 1 cm apart. An extension of the axle of each spirometer projects into the space between them and to each extension a small mirror is cemented.

The two spirometers are so placed that a single filament lamp throws a horizontal beam of light through the space separating the spirometer pans and into the camera. The mirror mounted on the axle of the spirometer connected to the blank plethysmograph reflects the beam of light from the lamp backward and onto the mirror attached to the spirometer connected to the true plethysmograph. The latter mirror reflects the beam of light forward through a focusing lens into the camera. Thus the optical system is so arranged that an increase in volume of the blank plethysmograph causes a downward deflection of the recording beam while an increase in volume of the true plethysmograph causes an upward deflection of the light beam. Any factor which changes the volume of both the true plethysmograph and the blank plethysmograph simultaneously to the same degree and in the same direction does not appreciably

Fig 4—Compensating spirometer recorder *a* Spirometer for recording volume change in the blank plethysmograph *a'* spirometer for recording volume changes in the true plethysmograph *b* metal pins containing fluid which seals the spirometers *c* metal pipes piercing the bottoms of the pans for connection with the plethysmographs *d* extension of the axes of the spirometers into the space between the pans *e* mirror facing backward *e'* mirror facing forward *f* focusing lens

alter the position of the recording beam. Since changes in room temperature and pressure affect the true plethysmograph and the blank plethysmograph equally and simultaneously, the errors caused by these changes are eliminated from the flow curve (Fig 5)

The mechanism for compensation is also demonstrated in Fig 6. If venous occlusion is made in both extremities simultaneously, the deflection of the beam

Fig. 5—Tracings illustrating the mechanism by means of which compensating spirometers compensate for fluctuations in room temperature and pressure. PV, Plethysmograph volume; B, base line; RT-RP, room temperature and room atmospheric pressure.

Fluctuations in atmospheric pressure were induced by suddenly opening and closing the door of the laboratory three times during each experiment. Such fluctuations are recorded in the RT-RP line. Note that they are about equal in each of the three experiments.

Blank spirometer. Tube leading to the plethysmograph was clamped so that only the spirometer recording volume changes in the blank plethysmograph recorded. Note that the major deflection of the spirometer is downward.

Plethysmograph spirometer. Tube leading to the blank plethysmograph spirometer was clamped so that only the plethysmograph spirometer recorded. The major deflection is now upward.

Compensating spirometer. Both the blank and plethysmograph spirometers recorded. The downward deflection of the former is neutralized by the upward deflection of the latter and no significant deflection of the recording beam occurs despite changes in atmospheric pressure.

Fig. 6—Tracings illustrating the mechanism of compensation by use of compensating spirometer recorder. Blood flow curves were taken from the left and right forearm of the same individual. Simultaneous venous occlusion of both arms caused only an insignificant deflection of the beam.

is insignificant, yet venous occlusion of the left or right limb alone will give a typical flow curve for that limb. It is clearly demonstrated that the deflection of the light beam by occlusion of the right arm is downward and its base line had to be made at the top of the camera slit. Venous occlusion of the left arm, however, deflects the beam in a direction diametrically opposite to that of the right and its base line, therefore, is made at the bottom of the camera slit. Both flow curves for the right and left forearms can be made separately and calculated as shown in Fig. 6. Simultaneous occlusion of both arms produces practically identical changes in volume in both arms at the same time and therefore the upward deflection of the beam produced by one arm annuls the downward deflection produced by the other. Hence, by the use of compensating spirometers simultaneous changes in the limbs similar in magnitude and direction are taken care of without significant error.

Maey Tambour —A Maey tambour with an optical system of recording is used to test for the presence of leaks. To test for leaks, the tube leading to the compensating spirometer from the plethysmograph is clamped. Enough air is injected into the plethysmograph to induce a pressure of 15 cm. of water and the deflection of the beam of light reflected from the rubber tambour is noted. A persistent fall in pressure is indicative of a leak in the apparatus.

PROCEDURE FOR MAKING AN AIRTIGHT SEAL BETWEEN THE LIMB AND THE PLETHYSMOGRAPH WITHOUT INTERFERING WITH THE CIRCULATION

The procedure that was used for making an airtight seal consisted of coating the part of the limb proximal to the plethysmograph with surgical jelly before inserting it into a thin rubber sleeve 8 to 10 inches (20.3 to 25.4 cm.) long. The sleeve fits loosely around the limb (Fig. 2). A disk of sponge rubber $\frac{1}{2}$ inch (1.3 cm.) thick and with a diameter equal to that of the inlet of the plethysmograph had a hole cut into it conforming to the contour of the limb but with a slightly greater circumference. The limb is slipped through the hole in the disk and the distal end of the rubber sleeve is everted over the rim of the disk. A bandage is wrapped snugly but lightly over the rubber sleeve and limb proximal to the disk. This helps to support the disk and sleeve, insure airtightness, and eliminate the presence of pockets under the sleeve. The distal surface of the rubber disk is coated with surgical jelly and clamped to the rim of the plethysmograph after insertion of the limb into proper position in the plethysmograph. The whole limb is then elevated sufficiently to insure venous drainage. An ordinary sphygmomanometer cuff used for children is wrapped around the limb about $\frac{1}{2}$ inch (1.3 cm.) proximal to the occluding disk and is used as a collecting cuff.

PHYSICAL CHARACTERISTICS OF THE APPARATUS

Comparison of Various Types of Recorders —In general, the various types of recorder used by previous investigators fall into two groups:

1. Those which maintain their deflection to a given increase of intra-plethysmographic volume by means of pressure built up within the plethys-

mograph by the increment of volume. The Marey tambour and glass spoon manometer are representative of this group. This group hereafter will be called pressure recorders.

2 Those which will tend to maintain their deflection without pressure though a slight change in intraplethysmographic pressure is necessary to cause the initial deflection. Biot's bellows, piston recorders and spirometers fall into this group. A single spirometer and compensating spirometers have been selected for study. This group hereafter will be called volume recorders.

The size of the tubing connecting the recorder to the plethysmograph should vary with the type of recorder. With a pure pressure recorder such as the glass spoon manometer, small bore pressure tubing yields the best results. With volume recorders such as the compensating spirometers, large bore tubing is essential. We have found tubing with an internal diameter of 1.5 cm. to be most satisfactory. Tubing of 1.00 cm. internal diameter or less introduces a definite lag in the recorder. Biot's and Abramson, Zizeka, and Marius⁶ also found wide bore tubing essential when using volume recorders.

Frequency of the Recorders—A Dile Schuster pump was so mounted that 5 cc. of air were injected into and extracted from the plethysmograph at the rate of about 50 cycles per second. The compensating spirometers failed to register these oscillations. The speed of the pump was then gradually decreased and it was found that the compensating spirometers responded to the alternate suction and pressure when these cycles occurred about twelve times per second. The pump was further slowed until the emission of the compensating spirometers was maximal to each cycle. This occurred at 3.3 cycles per second and was taken to represent the natural frequency of the recorder. By the same method the natural frequency of a representative Marey tambour was 10 cycles per second, of a glass spoon manometer 20 cycles per second, and of a single one of the compensating spirometers 3.3 cycles per second.

The Effect on Various Recorders of Different Volumes of Air in the Plethysmograph—The rubber tambour and glass spoon manometers gave increasingly higher deflections for the same increment of plethysmographic volume as the air volumes increased. Single spirometers and the compensating spirometer gave practically identical deflections no matter what the intraplethysmographic volume of air might be.

When the volume of air in the plethysmograph compensating spirometer unit was changed from 9.950 to 9.960 cc., a deflection of 9 cm. occurred. When the volume was changed from 52 to 62 cc., a deflection of 9.15 cm. occurred (Fig. 7).

Hence, if one uses a pressure recorder an individual calibration chart must be obtained for each subject investigated since arm volume varies with each individual. On the other hand, with a volume type of recorder one may use the same calibration chart for any subject.

The Effect of Various Recorders on Pressure Within the Plethysmograph—With a typical Marey tambour, slow injection of 10 cc. of water into the plethysmograph induced an intraplethysmographic pressure of about 90 mm. of water.

Slightly greater pressures were induced by the same amount of water injected into the plethysmograph when a glass spoon manometer was used for recording. With the compensating spirometer a change of 0.5 mm of water pressure will move the recorder appreciably. When properly balanced the compensating spirometer maintains a given deflection without appreciable change of pressure.

Fig. 7—The effect of varying plethysmographic volume on the deflection of compensating spirometers. PV, Plethysmograph volume; B, base line; PP, pressure in the plethysmograph recorded by a Marey tambour; RT-RP, room temperature and room atmospheric pressure.

A, Volume of the plethysmograph-compensating spirometers unit changed from 9,950 cc to 9,960 cc by the injection of 10 cc of air into the plethysmograph. The deflection of the recorder was 9.0 centimeters.

B, Plethysmograph excluded from the plethysmograph-compensating spirometers unit leaving a volume of 52 cubic centimeters. The injection of 10 cc of air into the compensating spirometers induced a deflection of 9.15 centimeters.

The Effect on Various Recorders of Changing Environmental Pressure and Temperature—Ellis⁹ in 1885, indicated that an air plethysmograph is very sensitive to changes of temperature. Turner,¹⁰ in 1937, re-emphasized this point. We have found that all four types of recorders studied were very sensitive not only to changes in environmental temperature but also to air pressure. Single spirometers and Marey tambours were particularly vulnerable to errors induced by changes in environmental pressure or temperature. In fact it was impossible to obtain accurate flow curves on a windy day or in a place where doors were continually being opened and closed. On the other hand, the compensating spirometers eliminate errors induced by changes of room temperature or pressure, as discussed in describing the recorder (Fig. 5).

CALIBRATION OF THE PLETHYSMOGRAPH, USING THE COMPENSATING SPIROMETER FOR RECORDING

We thought it of interest to compare calibrations of the plethysmograph by the usual method of injecting known volumes of fluid into the plethysmograph and by a method whereby the plethysmograph is perfused with known

pulsating flows By means of the Dale Schuster pump one can deliver very nearly constant pulsating flows of amounts of fluid varying from 0 to 500 cc per minute The pulse contour of the instrument simulates that of the heart We have been unable to find any reference to the calibration of a plethysmograph by the use of known pulsating flows

Method —

1 *Injecting Known Volumes of Fluid Into the Plethysmograph by Means of a Syringe or Burette* A section of rubber Penrose tubing was placed in the plethysmograph, extending through its entire length The tube was clamped at its distal end The other end opened to an outlet in the proximal end of the plethysmograph where it was connected to the delivery end of a certified 100 cc burette, accurate to 0.05 cc, and filled with water Increments of volume injected from the burette were then plotted against the actual deflections of the recording beam (Fig 8, line B) Rapid injection from a syringe or slow injection from the burette gave the same calibration curve

2 *Perfusing the Plethysmograph With Known Pulsating Flows* The Penrose tubing was arranged in the same way inside the plethysmograph except that the end which had been clamped was fastened to an inlet through the distal end of the plethysmograph A stopcock was inserted in the outlet of the Penrose tubing Water was perfused through the tubing by means of a Dale Schuster pump The perfused water was measured in cubic centimeters per minute at least twice before and once after each flow curve was taken The stopcock in the outlet was suddenly closed, thus trapping water within the Penrose tubing, and a tracing of the increase in intraplethysmographic volume per unit of time was obtained (Fig 9) Flow curves of perfused flows ranging between 10 and 400 cc per minute were then obtained and the slope of each flow curve was drawn Increments of volume of water collected were then plotted against actual deflections of the recording beam (Fig 8, lines A, C, and D)

Method of Measuring Unknown Flows Produced by a Mechanical Schema —

Having obtained a calibration curve one can deduce accurately the increase in volume within the plethysmograph from the resultant excursion of the recording beam Unknown flows produced by a mechanical schema are measured as follows The plethysmograph is perfused with an unknown pulsating flow delivered by a Dale Schuster pump as described previously under Calibration of the Plethysmograph The slopes of the flow curves obtained when compensating spirometers are used for recording are practically straight lines and therefore the flow may be calculated by any one of the following methods (1) slope of the flow curve, (2) retiral increment of volume per pulse beat, or (3) actual deflection of the recorder per unit of time All methods give identical results within the experimental error of about 1 per cent We have used calculations derived from the slope of the flow curve since this was found to be the most convenient method The slope of the flow curve is drawn A three, six or ten second interval of time is marked off along the base line of the flow curve from the point where the slope line intersects the base line From the point so obtained, a perpendicular is erected to intersect the slope line The length of

Fig 8—Calibration of compensating spirometers with flows of various magnitudes

Fig 9—Typical flow curve obtained by perfusing the plethysmograph with known pulsating flows and using compensating spirometers for recording PV, Plethysmographic volume recorded by compensating spirometers B base line PP plethysmographic pressure recorded by a Marek tambour (note that the maximal sustained pressure in the plethysmograph is 0.05 mm of water) RT-RP, room temperature and room atmospheric pressure

this perpendicular line represents the amount of air displaced from the plethysmograph into the recorder during the interval of time used. From the calibration curve, the length of the fore mentioned perpendicular line may be easily converted to cubic centimeters of volume added to the plethysmograph per unit of time and this figure then may be expressed as cubic centimeters of flow per minute.

Experimental Error of the Plethysmograph When a Mechanical Schema Was Used for Perfusion and the Compensating Spirometer Was Used for Recording—Hewlett and Van Zwaluwenburg,¹¹ in 1909 estimated that their apparatus came within 20 per cent of measuring true blood flow in favorable cases. On the other hand, Stead and Kunkel¹² in 1938, estimated the instru-

mental error of their plethysmograph to be $\pm 0.1 - 3$ per cent. However, they found it necessary to add 13 per cent to the flows calculated from calibration curves obtained by the injection of air into the plethysmograph from a syringe. Primzmetal and Wilson,¹⁷ using an adaptation of Lewis and Grant's¹⁴ instrument (1925), estimated the experimental error of the apparatus to be 15 per cent. Killian and Oelassen¹² estimated the experimental error of a modification of Hewlett and Van Zwaluwenburg's apparatus to be ± 15 per cent.

The compensating spirometer recorder was studied in detail concerning its accuracy in measuring flows within the usual limits of flow encountered in the human arm. The findings are shown in Table I. The person who calculated the flow from flow curves had no idea whatsoever as to what the actual flows were. The results may be summarized as follows. When compensating spirometers are used for recording pulsating flows produced by a mechanical schema, 98 per cent of the calculated flows lie between ± 2 and ± 4 per cent of the actual flow. 95 per cent of the calculated flows lie between errors amounting to ± 2 and ± 3.5 per cent, while 82 per cent of flows lie between ± 2 and ± 2 per cent of the actual flow. The average error in calculating flows was -0.88 per cent.

ANIMAL EXPERIMENTS DESIGNED TO TEST THE VALIDITY OF THE FUNDAMENTAL PRINCIPLES OF PLETHYSMOGRAPHY

Does the Plethysmograph Measure Blood Flow?—The increase in volume of a limb after inflation of a collecting cuff might be due to trapping of incoming blood within the limb, displacement of fluid and tissue distally from beneath the collecting cuff, or transudation of fluid from the capillaries to the tissues of the limb. In the estimation of blood flow by the plethysmographic method it is assumed that the trapping of incoming blood is the chief cause of the increase in volume of the limb. The initial portion of the flow curve represents displacement of fluid and tissue from beneath the collecting cuff and is disregarded in estimating blood flow as was discussed by Hewlett and Van Zwaluwenburg,¹⁶ or is eliminated from the flow curve mechanically, as discussed by Wright and Phelps,¹⁷ or manually, as discussed by Hewlett and Van Zwaluwenburg.¹⁸ Davis and Jones¹⁹ found that, after occlusion of the return of venous blood from the legs, edema formed in the leg at the rate of 0.017 cc per minute per 100 cc of tissue when the environmental temperature was 16° C. At 42° C 0.07 cc of edema fluid formed each minute per 100 cc of leg tissue. If one applied the latter findings to a human arm of 1,500 cc volume even in a hot environment, only about 0.18 cc increase in volume would occur during ten seconds after inflation of a collecting cuff. Krogh, Landis and Turner²⁰ found that fluid accumulated in tissue spaces when venous pressure exceeded 15 to 20 cm of water. When venous pressure exceeded 17 cm of water, the rate of filtration was directly proportional to the increase in venous pressure and an increase in venous pressure of 1 cm of water increased filtration rate by 0.0023 cc per minute per 100 cc of arm. For an arm of 1,500 cc volume, this filtration rate would yield a maximal increase in arm volume for

ten seconds of about 0.13 cubic centimeter. Lewis¹ found that venous pressure equaled a collecting cuff pressure of 49 mm. of mercury in thirty nine seconds.

It seemed highly probable from the foregoing investigations that incoming blood could be the only significant factor responsible for the increase in arm volume which occurs during the first ten seconds after a collecting cuff is inflated about the human arm. However, we have been unable to find any direct evidence that such is the case. Hence the following experiment was performed.

Fig. 10—Known flows of blood perfused through the isolated hind limbs of a dog by means of a heart lung preparation. PP, Pressure in the plethysmograph recorded by a Marey tambour. RT-PP, room temperature and room atmospheric pressure. PI, plethysmograph volume recorded by compensating spirometers. VP, venous pressure in the hind limbs of the dog. B, base line. Heavy vertical lines, time in seconds. Light vertical lines, time in one-tenth seconds.

Using a small dog under pentobarbital sodium anesthesia a heart lung preparation was made of the upper half of the animal. Then the animal was transected in the midlumbar region. The abdominal aorta and vena cava of the lower half of the animal were cannulated and the entire lower half of the animal was sealed in the plethysmograph with a diaphragm occluding the outlet of the plethysmograph. An inlet for arterial blood and an outlet for venous blood from the lower portion of the animal were passed through the diaphragm and joined to the above mentioned cannulae in the abdominal aorta and vena cava. The lower half of the animal enclosed in the plethysmograph was then perfused

with blood by the heart lung preparation. Occlusion of the venous return was accomplished by clamping the venous outflow tube from the lower half of the animal. Thus flow curves were obtained. A simultaneous record of venous pressure distal to the point of clamping the venous return was made (Fig 10). Actual flows in cubic centimeters per minute were measured by collecting the blood as it emerged from the venous return tube. Estimation of the blood flow from the flow curve checked closely with the actual flow (Table II). We also noticed that venous pressure began to rise at the instant the venous return tube was clamped (Fig 10). Furthermore arterial inflow was unimpeded by a back venous pressure of about 17 cm. of water.

TABLE II CORRELATION OF ACTUAL BLOOD FLOW THROUGH HIND LIMBS OF DOG AND FLOWS CALCULATED BY THE PLETHYSMOKYMOGRAPHIC METHOD

SUMMARY

A new recording device (compensating spirometer) was developed, analyzed, and compared with other types of recorders commonly used in plethysmography.

A new method for calibration of plethysmographs is described. Known flows actually collected in cubic centimeters per minute were compared with flows calculated from flow curves. When the compensating spirometer was used for recording blood flow, the discrepancy between actual and calculated values was small enough to permit the conclusion that this new device eliminates most of the errors inherent in other types of recorders and can be used for measuring blood flow in human extremities.

DEVICES FOR RAPID RECORDING OF MULTIPLE AND SPECIAL ELECTROCARDIOGRAPHIC LEADS

ABRAHAM LITBINSKY, M D , AND A. ALAN GOLDBLOOM, M D , F A C P
NEW YORK, N Y

PERHAPS the greatest advance in modern electrocardiography is the employment of special exploring leads (direct and semidirect) that are physically closer to a particular part of the heart and register more intimately its electrical activity. The theoretic importance of such leads was long recognized by workers in this field but for the sake of simplicity and convenience, so that electrocardiography could come into widespread use, the limb leads were emphasized as the exclusive standard. Now with the anterior surface of the heart being studied by multiple chest leads, the posterior surface and base by multiple esophageal leads, and the individual, separate chambers of the heart (such as the right auricle) by leads specially suited to the study, promise for real advance in electrocardiography is high. It is important, however, to determine what the particular usefulness of a special lead is and also which leads are so informative that they should by right be used routinely in electrocardiography, the added information will more than compensate for the extra effort in recording the tracings. Definite headway has been made in this regard, but much manual work such as obtaining normal standards for a given lead, comparing it with similar ones, and outlining its limits of usefulness still remains to be done. It was felt that this task could be expedited and made less unpleasant if special apparatus were designed to accomplish this type of multiple lead recording with speed. The apparatus to be described* is flexible enough to record speedily almost every lead that has been proposed to date, and should be useful not only in this preliminary period when the standard of special multiple leads is being established, but also later in the routine recording of the multiple lead electrocardiogram which promises to be the tracing of the future.

Switch Box—The switching device which permits rapid recording of multiple leads without the moving of wires on the patient or the machine is shown in Fig. 1. It consists of a main selector switch and two auxiliary switches which are interposed between the patient and the electrocardiograph. All manipulations for the selection of leads are accomplished at this switch, the electrocardiograph always recording the selected lead on its fixed Lead II setting. Five shielded wires run from the patient to the switch, one from each extremity (the right leg being used as a ground when the other three extremities are connected to the Wilson central terminal) and a fifth one from either the precordium or any other area to be explored. From the switch run the RA, LA, and LL wires of the electrocardiograph at connector marked ECG. Although only Lead II (RA and LL) is necessary for the recording, the switch makes all its grounding connections for any selected lead through its LA terminal. This insures a base line free of A C and other extraneous interferences, so that the switch box may be used with the newer types of direct writing electrocardiographs that are so sensitive to A C interference.

From the Medical Service, Beth Israel Hospital.

Received for publication Oct. 14, 1947.

*Made by Medical Designs, Brooklyn, N. Y.

The main selector switch permits recording not only of the conventional leads but also of the chest leads most commonly employed: precordium right arm (CR), precordium left arm (CL), precordium left leg (CF), and precordium Wilson central terminal (V, in which all three extremities are connected through equal 5,000 ohm noninductive resistances to form a point of zero potential).¹ There are also settings on the switch for obtaining the potential of the right arm, left arm or left leg, that is the unipolar limb leads with the Wilson terminal as the indifferent electrode (V_R , V_L , and V_F). The complexes obtained with the V_R , V_L , and V_F leads tend to be small. Tracings of higher amplitude are secured by shunting out of the

Fig 1—Switch box

circuit the 5,000 ohms resistance from the extremity that is being explored while keeping the resistors of the other two extremities in the Wilson hookup. The augmented Wilson unipolar leads can be recorded by turning the switch to the aV_R , aV_L , or aV_F settings.

As seen in Fig 1, there are two adjunct switches used in conjunction with the main selector switch, the left hand one is for multiple leads taken from the front of the heart (precordial), and the right hand from the back of the heart (esophageal). For taking single precordial leads the exploring electrode (fifth patient wire) is used and the precordial switch is set at precordial (STD). If the multiple precordial lead belt, to be described later is used, the tracings from the six precordial electrodes are taken in succession by use of switch setting

1 to 6 inclusive. The main switch permits a choice of four indifferent points for precordial registration, that is, the right arm (CR), the left arm (CL), the left leg (CF), and the Wilson terminal (V). For esophageal tracings the eleven terminal esophageal lead, to be described later, is plugged into the selector switch and tracings from each of the eleven esophageal levels are taken in succession on the appropriate setting of the esophageal switch. Here there is a choice of five indifferent points for coupling with the esophageal lead: right arm (E_R), left arm (E_L), left leg (E_I), precordium (E_C) or Wilson terminal (E_V). For the past thirteen years we have been accustomed to recording the esophageal lead with the exploring electrode connected to the RA terminal and the indifferent electrode to the LL terminal, so that the resultant tracing (taken the same way as Lead II) should resemble the

Fig. 2—Multiple precordial lead belt

precordial and conventional leads. This direction was followed by Brown³ but is opposite to that used by Nyboer,⁴ Graybiel and White,⁵ and others. It is a simple matter to reverse the direction of the tracing by use of a simple throw switch marked Polarity Reverse on the left side of the switch box. This switch reverses the polarity not only of the esophageal lead, but also of any of the other leads when desired.

Multiple Precordial Belt—A modification of the elastic rubber belt described by Geiger and Goerner⁶ has been found very effective in the rapid recording of multiple precordial leads (Fig. 2). The belt is made of high quality flat rubber belting about 1 inch wide and 42 inches long. Six flat German silver disk electrodes about 3 cm. in diameter are spaced 4 cm. apart toward one end of the belt. Soldered wires run from the disks through a six prong Jones connector and join the other five leads to form the eleven lead patient's cable (Fig. 3).

This cable plugs into the switch box at the connector marked To Patient. A hook on the free end of the strap fits into the proper hole punched in the belt making for easy adjustment of the elastic belt to the size of the chest. The only precordial placements that need be determined are the positions of electrodes 1 (right edge of sternum in the fourth interspace) and 6 (midaxillary line in the fifth interspace). The average technician locates these two points

FIG. 3—Eleven lead patient's cable

easily enough. The other four electrodes lie automatically at equal distances from 1 to 6. The saving in time with this technique is appreciable. For still greater speed the following practical points may be noted. The rubber strap is laid across the arms of the electrocardiographic chair before the patient seats himself, avoiding the clumsy procedure of passing the belt around the patient's back. A thin layer of electrode paste is applied to

the six electrodes. The sixth electrode is first placed in the proper position. With the free end of the belt held in the left hand, the belt is put under tension with the right hand until electrode 1 has reached the proper position (right sternal edge). It is only then that the electrodes 1 to 5 are permitted to touch the chest. One can thus see the fifth disk falling into its proper position, then the fourth, the third, and so forth. If the amplifier type of electrocardiograph is used, no further rubbing of the skin is necessary. With the string type, the electrodes may have to be rubbed up and down to reduce skin resistance, particularly if the chest is hairy. The size of the female breast introduces no difficulty with this technique, for the breasts are always lifted and the belt is set in position beneath the mammary folds.

Fig 4—Eleven-electrode esophageal lead

Esophageal Lead—The esophageal lead designed for this study (Fig 4) is similar to Nyboer's.⁴ The essential difference is that by an improvement in production technique an eleven-electrode lead can be built into a No. 12 Fr Levin tube, whereas to date this could be accomplished only in the larger 14 Fr or 16 Fr size. The 12 Fr tube can be readily passed, even in children. A special Levin tube which has no openings in the end is used so that no secretions can penetrate to the inside. Eleven narrow German silver rings spaced 3 cm apart are attached to the tube. A separate insulated wire leads from each ring through the tube to its appropriate post in a twelve-prong Jones connector plug. The twelfth prong of the plug connects to the electrical shielding of the cable that runs to the switch box (not shown in Fig 4). The technique in use with the esophageal lead is as follows. The patient is first reassured about the safety of the procedure. The rubber tip of the esophageal lead is lubricated for about an inch or two with a little mineral oil. Through the more patent

nostril the tube is rapidly passed beyond the posterior pharynx, which is likely to be the most sensitive part, down into the esophagus. The patient is asked to sip some water through a straw or drinking tube while the lead is being passed. This preoccupation with drinking permits the lead to be passed within about ten seconds to the proper level (the lowest electrode being placed 55 to 60 cm. from the nares, as indicated by a mark on the tube). It is rarely necessary to use a local anesthetic for nose or pharynx. The patient is instructed to take a deep breath if uncomfortable or nauseated. In general, within a minute the patient will have become calm after the initial excitement of passing the tube. It will take, however, another five minutes or so for the esophagus to make its adjustment to the presence of the Levin tube in its lumen. During this time the position of the esophageal electrodes may be checked fluoroscopically if desired and the other connections can be made from the switch box to the patient's extremities and precordium. By the time the conventional leads and precordial leads have been recorded, the esophageal lead can be taken from each of the eleven esophageal levels in succession, using the esophageal switch. This five or ten minute waiting period after passing the esophageal lead, as well as the electrical shielding of the esophageal cable cuts down the drifting of the base line that is such a disturbing feature of esophageal electrocardiograms. It is to be noted that with the eleven electrodes spaced 3 cm. apart the entire base and the posterior aspect of the heart are explored as far as the esophagus permits without the necessity of moving the esophageal lead up or down from its original placement. In contrast, most esophageal leads used until now have employed a single or only a few electrodes and have had to be manipulated up and down the esophagus to cover the electrical field desired. The consequent retching and esophageal contractions cause much drifting of the base line and numerous artifacts in the tracings. The amplifier type of machine is better suited in general for the recording of esophageal electrocardiograms because of the high resistances found in the esophagus. On the other hand we have taken very satisfactory tracings using the eleven electrode esophageal lead and a standard string galvanometer.

COMMENT

The devices outlined are being utilized in an extensive study of the usefulness of the many special and multiple leads suggested for the more intimate exploration of the heart and its separate chambers. Our findings will be reported at a later date when our data are more complete. It is considered worth while, however, to describe at this time the different devices designed to speed up the investigation, for similar studies must be made by numerous investigators and the findings correlated before a proper evaluation can be made of the usefulness of any proposed lead. The end in view of such studies is the establishment of the value of certain leads to the point where their inclusion in routine electrocardiography would be justified. There are other leads which, although not of such universal significance as to become routine may still be found most suitable for a special study of a particular part of the heart. Thus the exact usefulness and also the limitations of a derivation such as the esophageal lead, coming in contact with the left auricle and the base of the left ventricle, could be established. This type of study is tedious and time consuming, any device that simplifies the procedure appears to us worthy of description.

The main selector switch with its adjunct multiple precordial and esophageal switches permits the rapid recording of practically all leads which have been proposed to date. The multiple esophageal and precordial leads can be connected further with a number of points as the indifferent electrode (right arm, left arm, left leg, Wilson central terminal, etc.), and the value of these different derivations can be compared. Although from the theoretic point of

view it may be best to couple all exploring leads with the Wilson terminal, empirically we, as well as others, have found instances in which other derivations were more informative. Whichever derivations will stand the test of time, it is likely that they can be easily registered with the multiple switch box described. Great pains have been taken to shield all the leads used in this study so that the devices could be employed with any electrocardiograph, even the direct-writing electrocardiographs that are so sensitive to A C interference. The machines that incorporate the automatic principle of bringing the beam to the mid-line before switching to the next lead are particularly suitable to the rapid recording of multiple leads. Here one need only press the automatic button and turn the multiple lead switch from one position to the other, and the machine is ready within a few seconds to record the new selection.

The technique described for taking multiple precordial leads is similar to the one used by Geiger and Goerner¹ and is advocated because of its simplicity and speed. Our experience with this belt technique almost exactly duplicates theirs. The difference between records obtained with this technique and the individual placements advocated by the American Heart Association² appear minimal and of little, if any, clinical significance. Results can be duplicated better with the belt than with the six individual placements, whether the physician or the technician determines them. Furthermore, in the belt technique, the fixed relation of the electrodes to the thorax rather than to the heart appears more sound, theoretically, in the study of many aspects of heart disease (axis deviation, bundle branch block, cardiac hypertrophy) than does the standard method.

The esophageal lead which we introduced in 1934³ has not yet been widely employed, mainly because of technical difficulties. These have been overcome largely by the new design of the tube which can be passed easily enough to be used when indicated in any case except perhaps in terminal decompensation or during the first few weeks of a coronary occlusion. The switch which permits rapid recording from each of the eleven esophageal levels in succession saves so much time that the taking of an esophageal lead no longer can be looked upon as a formidable procedure. Once the physician convinces himself by actual trial that this is true, he can readily transmit this confidence to the patient, and the field of usefulness of the esophageal lead widens immeasurably.

SUMMARY AND CONCLUSIONS

Three devices designed for the rapid registration of multiple leads are described. The multiple switch box with a limb lead selector, multiple precordial lead selector, and multiple esophageal lead selector is the main device. Aside from the different chest leads (CR, CL, CF, and V), Wilson's unipolar limb leads and augmented unipolar limb leads can be obtained readily. A single precordial lead or six multiple precordial leads can be coupled with any of four indifferent points, and the eleven-electrode esophageal lead with any of five indifferent points.

An elastic multiple precordial lead belt is described which facilitates the rapid recording from six precordial areas by plugging into the switch box.

A thin eleven electrode esophageal lead which plugs into the selector switch is described. The procedure of recording an esophageal lead has been simplified so that it may be applied to any case except serious acute cardiac incidents.

It is hoped that these devices may prove of use to other investigators who are studying the comparative usefulness of special and multiple leads in electrocardiography.

We are deeply indebted to the late Dr. Frank Liberson and Dr. I. W. Held whose constant inspiration made this study possible.

DETERMINATION OF VOLATILE REDUCING SUBSTANCES
(ALCOHOL OR ETHER) IN BLOOD AND GASES USING BARIUM
DIPHENYLAMINE SULFONATE AS AN INDICATOR FOR
CHROMIC ACID TITRATION

ALLAN HEMMINGWAY, LEO ALLIN BERNAT, AND JOSEPH MASCHMEYER
MINNEAPOLIS, MINN.

IN THE determination of volatile reducing substances (primarily alcohol and ether) in blood or in air the usual procedure consists of absorbing these volatile organic substances in sulfuric acid, adding a known amount of potassium dichromate, and oxidizing the alcohol or ether to acetic acid by the chromic acid. The excess dichromate is then determined either colorimetrically or by titration.

With the colorimetric method as used by Gibson and Blotner (1938) and Newman and Abramson (1942), the organic substances are oxidized to acetic acid by chromic acid and the dichromate residue, consisting of chromic acid and chromic sulfate, is determined by absorption of light in the region of wave length 440 to 480 millmicrons. This method, while rapid, has the three following disadvantages: (1) The relation between the logarithm of the galvanometer reading and ether (or alcohol) concentration is not a straight line but is slightly convex. (2) Since light is absorbed by both dichromate and chromic sulfate it is necessary to calibrate the apparatus with ether (or alcohol) solutions of known concentration. Due to the highly volatile nature of ether and alcohol and the affinity of alcohol for water, the preparation, storage, and dispensing of standard solutions for precise work is a task requiring unusual precautions in technique. (3) For small quantities of blood the dichromate chromic sulfate mixture has low spectrophotometric sensitivity.

The titration method has been used widely. Excess dichromate after oxidation is titrated with a suitable reducing solution and a redox indicator. Iodometric titration of excess nonreduced dichromate was used by Shaffer and Rozum (1923), Newman (1936), McNally and Coleman (1944), Widmark (1922) and others, while Harger (1935), Cavett (1938), Levine and Bodansky (1939), and Fisk and Nelson (1941) preferred ferrous sulfate solution containing methyl orange. The methyl orange-ferrous sulfate solution was used in preference to the older iodometric titration because of the unsatisfactory titration end point of the older method.

In the present investigation the colorimetric method using the Evelyn colorimeter was used and was rejected for the reasons already given. Titration

From the Department of Physiology, the Medical School, University of Minnesota.
Received for publication Jan. 16, 1947.

using the ferrous sulfate methyl orange mixture, was tried but rejected because the titration end point was not sharp. The redox indicator barium diphenylamine sulfonate was next investigated, using the titration procedure described by Kolthoff and Sandell (1938). This indicator, in the presence of phosphoric acid, gave a sharp end point with the color changing from violet blue to colorless. For titrating a sample of dichromate equivalent to one milligram of ether with 20 mls of a solution of ferrous sulfate a fraction of a drop of the reducing solution was sufficient to cause a sudden and striking change of color. This indicator was adopted for the determination of alcohol and ether in blood or in air with the procedure which will be described.

METHODS

Reagents—Ferrous sulfate, stock solution. Dissolve 50 Gm of $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ in 150 ml of water. Add 30 ml of concentrated sulfuric acid and dilute to 250 milliliters. In a stoppered flask the solution will undergo only slight oxidation.

Barium diphenylamine sulfonate, stock solution. Dissolve 0.1 Gm barium diphenylamine sulfonate in 100 ml of water.

Ferrous sulfate indicator solution for titration. To 15 ml of the ferrous sulfate stock solution and 20 ml of the indicator stock solution add water to 2000 milliliters.

Potassium dichromate standard solution. Weigh out exactly 5.295 Gm $\text{K}_2\text{Cr}_2\text{O}_7$ (Mallinckrodt's analytical reagent), dissolve in water and dilute to one liter. One milliliter of this solution is equivalent to 1 mg ether.

Sulfuric acid, C P Concentrated

Phosphoric acid, C P 85 per cent

Procedure for Determining Ether in Blood—Widmark flasks (Cavett 1938) of 50 ml capacity with T 24 standard tapered Pyrex stoppers were made (Fig 1, A). It is desirable in preparing these flasks to make the glass rod by means of which the cup is suspended from the stopper as short as possible. This prevents the cup (2.5 ml capacity) from dipping into the chromic acid at the bottom of the flask.

To determine ether in blood the blood is drawn into a syringe with a drop of saturated potassium oxalate filling the needle and needle tip of the syringe. The blood is drawn with care to exclude bubbles in the syringe and is discharged into a two way stopcock pipette which contains approximately 0.25 ml of water in one arm (Fig 1, A). This pipette is made to contain approximately 1 ml in the lower arm. The volume of the lower arm is carefully determined with mercury or standard solution. Blood is discharged from the syringe as shown in Fig 1, A, and it ascends in the lower arm through the stopcock to the upper arm which does not contain the water. Approximately 0.5 ml of blood will ascend above the stopcock. The blood exposed to air as it ascends in the pipette will have lost ether to the air above its surface. This blood will be rejected. The stopcock is now closed, the syringe removed from the pipette and the lower

tip of the pipette held above the cup of the Widmark flask. The stopcock is turned to the arm containing the water, the blood is drained into the Widmark cup and is washed from the pipette with the 1 ml of water. The Widmark flask is stoppered immediately. A syringe pipette also has been used and found to be satisfactory.

Either 10 or 15 ml of standard dichromate solution from a dispensing burette are placed in the bottom of the Widmark flask and 30 ml of concentrated sulfuric acid are added. Similar quantities of dichromate and sulfuric acid are measured out for a blank and placed in a glass-stoppered 50 ml Erlenmeyer flask. The blood and wash water are placed in the Widmark cup as

FIG. 1—A, Blood pipette and syringe; Widmark flask; B, gas sampling bulb and ether absorber; C, burette for storage and dispensing of solutions with volatile solutes.

described and both the Widmark flask and the Erlenmeyer flask transferred to an oven at 80° C for four hours. The solutions are removed then and it will be observed that the blood has hardened to a cake by evaporation. After cooling, 3 ml of concentrated phosphoric acid are added and the solutions are titrated in the same flasks with ferrous sulfate containing diphenylamine sulfonate. The number of milligrams of ether in 100 ml of blood is given by the formula

$$\text{Ether (mg) in 100 ml of blood} = \frac{T_n - T_v}{T_n - 3e} \cdot \frac{100}{V} \cdot N$$

where T_B is the titration value of the blank (milliliters ferrous sulfate solution) T_x , the titration value of the unknown, V , the volume of the sample to be analyzed, N , the number of milliliters of the standard dichromate solution, and e , the reducing equivalent in milliliters of ferrous sulfate solution of 1 ml of concentrated sulfuric acid which is determined as explained later.

Procedure for Determining Ether in Air—The air ether mixture is collected in a gas sampling bulb of approximately 60 ml whose exact volume is determined by calibration. The sampling bulb has a one way stopcock at the bottom and a two way stopcock at the top and is connected to the bulb as shown in Fig. 1 B. The upper stopcock of the gas sampling bulb is joined with a short rubber connection to a glass capillary tube which is then connected to a long 100 ml tube (an old 100 ml burette can be used for the purpose). The 100 ml tube has a stopcock at the top and bottom, and at the start is filled by suction to the upper stopcock with 50 per cent sulfuric acid. The gas from the sampling bulb is transferred to the long absorber tube and displaces the sulfuric acid. After all the gas has been transferred approximately 10 ml of ether free air are washed from the stopcock at the top of the sampling bulb through the connecting tube to the absorber. The stopcocks at the bottom and top of the absorber are closed the connecting tube is disconnected from the sampling bulb and the absorber is shaken for about one minute and allowed to stand ten minutes. The contents of the absorber are then transferred to a 50 ml volumetric flask, the absorber is washed with approximately 5 ml of 50 per cent sulfuric acid which is transferred to the volumetric flask and the flask is made up to 50 ml with 50 per cent sulfuric acid. Three milliliters of the contents of the volumetric flask are placed in a glass stoppered Erlenmeyer flask containing 1.50 ml of the standard dichromate solution, the flask is allowed to stand at room temperature for thirty minutes. This solution and a flask containing 3 ml of 50 per cent sulfuric acid and 1.00 ml of standard dichromate are titrated at the same time. The amount of ether in 100 ml of the air ether mixture is computed from the following formula

$$\text{Ether (mg) in 100 ml of air ether mixture} = \frac{T_B - T_x}{T_B - 1.5e} \cdot \frac{100}{V} \cdot \frac{50}{N}$$

where T_B is the titration value of the blank in the flask T_x , the titration value of the unknown, e the reducing equivalent of the sulfuric acid used V the volume of the gas sampling tube in milliliters N the number of milliliters of dichromate, the volume of the volumetric flask 50 ml and the pipette volume 3 milliliters.

Test for Reducing Power of Sulfuric Acid—Sulfuric acid contains a variable amount of reducing material, possibly SO_2 which reduces ferrous sulfate. In many samples of sulfuric acid there are no reducing substances. For accurate analyses an estimate must be made of the reducing power, e , of the sulfuric acid used in the procedure. This is done by placing in a series of six Erlenmeyer flasks 1 ml of the standard dichromate and 0, 1, 2, 3, 4, and 5 ml of

concentrated sulfuric acid To each flask, 3 ml of concentrated phosphoric acid are added and the solutions titrated The titration values are plotted against milliliters of sulfuric acid, and the reducing power, e , per milliliter of sulfuric acid determined This titration must be made for each new bottle of sulfuric acid used The value of e has not exceeded 0.5 ml of the ferrous sulfate solution used for titration All samples of phosphoric acid tested were found to be free of reducing substances

Test for Oxidation of Acetic Acid—In the Nielou's oxidation of ether and alcohol, as given by the following equations, two assumptions are made, namely (1) that all of the alcohol (or ether) is oxidized to acetic acid, and (2) that none of the acetic acid is oxidized

If these assumptions are valid, the oxidation proceeds as shown by the equations and an equivalence can be computed whereby 1 milligram of ether is equivalent to 5.295 mg of potassium dichromate and 1 mg of alcohol is equivalent to 4.259 mg of potassium dichromate It is necessary to determine, as pointed out by Shaffer and Ronzoni but ignored by many later workers, whether or not oxidation is complete and whether or not acetic acid is oxidized A number of experiments were performed to determine whether acetic acid was oxidized under the conditions of the experiment A solution of acetic acid containing 1.68 mg of acetic acid per milliliter of solution was prepared and tested for oxidation Four solutions, each containing 1 ml of standard dichromate solution and 3 ml of concentrated sulfuric acid, were prepared (in quadruplicate) and treated in the following way (A) Blank—titrated with ferrous sulfate—diphenylamine sulfonate solution at room temperature, (B) 1 ml of acetic acid solution added and titrated at room temperature, (C) Blank (chromic acid alone), heated for four hours at 80° C, (D) 1 ml of acetic acid solution added and heated in an oven for four hours at 80° C The results are contained in the following table

SOLUTION	CONDITION	TITRATION VALUE	EQUIVALENT ETHER (MG)
A Blank	room temperature	23.80	1.00
B Blank with 1 ml of acetic acid	room temperature	23.83	1.00
C Blank	80° C for 4 hr	23.09	1.00
D Blank with 1 ml of acetic acid	80° C for 4 hr	22.99	1.009

It is to be noted that the oxidation of acetic acid equivalent to 1 mg of ether is less than 1 per cent in terms of the error involved in ether analysis, and hence is so small that it can be neglected However, on comparing A and C it is to be noted that there is a loss of approximately 3 per cent in the oxidizing power of chromic acid when kept for four hours at 80° C This result requires that the blank chromic acid be treated in the same manner as the chromic acid which absorbs ether, namely being kept with the ether absorbing solution at 80° C for four hours

Preparation of Standard Solutions of Ether and Alcohol—The method used does not require standard solutions of ether or alcohol. The reason for this is the sole standard is the potassium dichromate solution. For assessing the method, certain standard solutions are necessary and the preparation of these into the certain difficulties. Solutions of ether and alcohol are difficult to prepare due to the high volatility of ether and alcohol. Solutions are difficult to prepare due to the high volatility of ether and alcohol. Solutions are difficult to prepare due to the high volatility of ether and alcohol.

The best method of storing and dispensing the solution was found to be a glass bottle with a cork in Fig. 1. Three bottles were prepared for a pure ether solution made from a 5 ml. Mohr pipette, one for a 10 ml. Mohr pipette and a 25 ml. Mohr pipette for an alcohol solution containing 10 mg. of ether per milliliter. Pure ether was distilled from calcium chloride and the water removed from calcium chloride. A stock solution of 100 ml. of ether containing 10 mg. per milliliter was made by weighing 1.0 g. of ether and 2.0 g. into 100 ml. of water in a volumetric flask. The solution was rapidly diluted to volume, stoppered, shaken and allowed to stand overnight. Then five milliliters of the solution were drawn from the bottom of the flask and transferred to the top of a standard flask and the remainder was discarded. A solution of ether in blood was made by adding 10 ml. of the standard solution to 50 ml. of blood and by withdrawing 10 ml. of this solution from the bottom of the volumetric flask in order to obtain pure ether. The procedure was adopted for many trials of ether in blood and was found to be a satisfactory method.

Test for Recovery From Prepared Solutions of Ether in Blood—A recovery test from prepared solutions where ether concentration is known is a test of determining an example of recovery of ether and volatile ether or of ether. At a temperature of 50° C. it was found that 1 ml. of ether distilled from 1 ml. of a solution of ether in water in two hours. Distillation must be slow and required four hours. Oxidation of ether in chromic acid prepared as described is complete in thirty minutes at room temperature. Solutions of ether in blood were prepared and the recovery of ether measured. The results were as follows: for a solution made to contain 100 mg. ether per 100 milliliters of blood A 105.0 mg. per 100 ml. solution B 104.0 mg. per 100 milliliters.

Organic volatile matter in 100 ml. blood was 25 milligrams.

Corrected value for ether in blood was 102.5 mg. per 100 milliliters. An error of 2 per cent was involved which was probably due to the errors involved in preparation of the standard solution.

Distillation Time—A test was made to determine the time required for distillation in the oven at 50° C. The time will vary with the surface area and volume of the two solutions in the Winkler flask. The time for the ether-containing solution in the cup and the receiving solution (chromic acid) at the bottom of the flask. Following are the data on recovery of ether from a standard solution of ether in blood.

2 hours in oven	2 per cent
3 hours in oven	75 per cent
4 hours in oven	92 per cent

With the Widmark flasks used, four hours in the oven were required for complete distillation although distillation was 90 per cent complete after two hours. Distillation is not complete until the blood sample is hard and caked.

DISCUSSION

The Widmark method of determining ether (or alcohol) in blood has the advantage of eliminating a distillation process, which permits a considerable saving of time. It does require, however, a wait of four hours for ether to diffuse from the solution in the cup to the receiving solution at the bottom of the flask. Where speed in analysis is not essential, the convenience of this method is an advantage. The four-hour period in the oven will cause a loss of the oxidizing power of the dichromate which will amount to as much as 5 per cent. This can be corrected for by placing the blank chromic acid in the oven with the ether sample. The method used by Levine and Bodansky (1940), in which the sample of blood containing alcohol was absorbed by a filter paper and suspended within a flask containing chromic acid, was found to be unsatisfactory due to the dropping of invisible particles of dust or dry material from the paper into the chromic acid (Anderson, 1942). Rapid transfer is effected by this method but irregular results are obtained. In using chromic acid for absorption of less than milligram quantities of ether, it is necessary to use scrupulously clean glassware and to avoid dust particles. All open flasks must be covered and only the cleanest of stirring rods, kept dust free, can be used. It was the customary practice in a series of titrations to discard the first blank titration which was usually low, probably due to dust. If rapid analysis is necessary and if the delay due to ether transfer in the Widmark flasks is to be avoided, a distillation similar to that described by McNally and Coleman (1944) could be used.

A precaution which is recommended is that chromic acid cleaning solution be avoided in cleaning the glassware. Trisodium phosphate cleaning solution has been found to be satisfactory for this purpose.

The reagents to be dispensed, including ferrous sulfate, sulfuric acid, phosphoric acid, and standard dichromate, are all delivered from burettes. A 2 ml burette is used for the standard dichromate, and 50 ml burettes are used for the concentrated acids. These acids are delivered to the burettes from an all-glass reservoir and connecting system by pressure. Phosphoric acid is used as a stopcock lubricant for the burettes containing the strong acids, but is not highly satisfactory since a slight sticking of the stopcocks will occur. Some of the silicone greases might be useful for this purpose. A minimum amount of grease must be used on the stopcocks of the burettes containing the potassium dichromate and the ferrous sulfate.

In using the redox indicator, barium diphenylamine sulfonate, the indicator can be added in a constant amount to the dichromate solution. The indicator itself undergoes oxidation and reduction, hence a correction is theoretically required. This correction cancels out and the step in the analysis which requires addition of the indicator can be eliminated if the indicator is added to the

ferrous sulfate reducing solution. The total reductant then includes both the indicator and the ferrous sulfate and the mixture is standardized against a known amount of potassium dichromate. This procedure has the disadvantage that when only a small amount of chromic acid remains unreduced in the solution and only a few milliliters of reducing solution are needed the amount of indicator present may be insufficient to produce a well defined color. This difficulty can be avoided by adding sufficient excess dichromate which is always a safe procedure in any event since if the amount of dichromate is insufficient for the ether present the analysis is spoiled. An estimated excess of 0.2 to 0.5 ml of standard dichromate which required 4 to 10 ml of the ferrous sulfate indicator solution was found to be satisfactory.

In evaluating the present method in comparison with other methods described in the literature (Levine and Bodansky, 1939) the present method is found to be unique in possessing a sharp well defined and highly chromogenic end point. The titration method relies for standardization and calibration on a single standard solution of potassium dichromate which is a reagent readily available in a highly purified form and therefore makes an excellent standard. It is not necessary, as is required with the colorimeter method to calibrate with standard solutions of alcohol or ether. These are required in the colorimeter method because the color developed after reduction of part of the chromic acid by alcohol or ether is due to both dichromate and chromic sulfate. Furthermore with the colorimeter method it is not possible to use the completely oxidized dichromate and the completely reduced dichromate that is chromic sulfate as limiting values on a calibration graph since the calibration curve of logarithm of colorimeter reading plotted against ether (or alcohol) concentration is not a straight line and the deviation is greatest at the limits.

SUMMARY

A method for determining ether (or alcohol) in blood and gas mixtures is described. The method consists of a distillation in a Widmark flask with oxidation of the transferred alcohol or ether by chromic acid. Excess chromic acid is titrated with ferrous sulfate using barium diphenylamine sulfonate as an indicator.

RECTAL ABSORPTION OF PENICILLIN

EMANUEL L. MANDL, M.D.,* CHICAGO, ILL., AND
JAMES D. THAYER, Ph.D.,† STATEN ISLAND, N. Y.

SINCE the early days of the penicillin era destruction by fecal enzymes has been regarded as one of the main obstacles to effective low intestinal absorption of penicillin.¹⁻¹⁰ Results of more recent investigations on this subject are contradictory. Absorption from ligated loops of the colon of rats was determined¹¹ to be nearly the same as that from the duodenum. Other authors⁶ reported the penicillin uptake from isolated segments of the large intestine of rats to be inferior to duodenal absorption. In a man with a fistula of the colon penicillin activity in blood and urine was negligible (23 per cent urinary recovery) after introduction through the fistula of 0.3 million units in solution.⁸ In apparent contrast to these observations Loewe and associates¹² obtained therapeutic serum concentrations with the rectal use of penicillin suppositories (up to 0.77 unit per milliliter one hour after insertion of one million units). The statement by Davison¹³ that 'rectal suppositories will maintain a therapeutic level for twenty-four hours' is probably based on those findings. Stimulated by this same report Barch and co-workers¹⁴ introduced penicillin in aqueous solution rectally only to find no demonstrable blood level. Nevertheless, a paper from the Mayo Clinic¹ which appeared while the present study was in progress listed results comparable to Loewe's, as produced with penicillin suppositories.

In view of these discrepancies and because of the lack of conclusive information on quantitative penicillin absorption from the rectum the present work was undertaken.

EXPERIMENTS AND METHODS

All experiments were performed on adult male human subjects between the ages of 18 and 50 and on two children as indicated below, all of whom had no apparent organic intestinal disorder. Penicillin was administered rectally in cocoa butter suppositories, cocoa butter capsules, gelatine capsule, and by microclyster and insufflation and the resulting antibiotic activity of blood and urine was determined. For reasons of comparison parenteral and oral administration were also studied.

The suppositories (Table I) were made by mixing dry penicillin with cocoa butter at 50 to 60° C. to which was added a small amount of peanut oil or kaolin in the first few trials and 2 per cent beeswax in the later ones. The streptomycin suppositories used in four

The first part of this report was presented at the Thirty-First Annual Meeting of the Federation of American Societies for Experimental Biology in Chicago, May 27, 1947 (abstracted in *Federation Proc.* 6: 353, 1947, Part II).

Received for publication July 2, 1947.

*Surgeon (R) U. S. Public Health Service, Chief of Medical Service, U. S. Marine Hospital.

†Bacteriologist, U. S. Public Health Service, Venereal Disease Research Laboratory, U. S. Marine Hospital.

trials (Table I, Cases 12 to 15) were prepared in the same manner, two such suppositories, each containing 0.25 Gm., were inserted two hours before a penicillin suppository. A cleansing saline enema was given in this and in the subsequent group of experiments one to three hours before the test to those subjects in whom satisfactory elimination had not occurred earlier the same morning. No such enemata were used in any of the following experiments.

A microclyster (Table II) was prepared by dissolving penicillin in physiologic saline (100,000 units per 5 ml.). Injection into the rectum was performed through a rubber catheter, the patient remaining on the side in order to prevent leakage.

Cocoa butter capsules were made by placing dry penicillin in the center of the cold mold which had been covered by a layer of hardened cocoa butter. One or two drops of the melted oil closed the opening, forming the base of the suppository capsule which was then kept under refrigeration until immediately before administration (Table III).

Insufflation of penicillin was carried out through an anoscope into the rectum of five subjects (Table VI). A small amount of water soluble lubricant was applied to the outside of the instrument before its introduction.

For penicillin assay as shown in Tables I, II, and V, the Food and Drug Administration cup plate method¹⁶ was employed in the urine and a modification of Rammelkamp's method¹⁷ in the serum.* In the latter determination, the susceptibility of the lyophilized hemolytic streptococcus strain used as the inoculum averaged 0.015 unit per milliliter.

Penicillin assay listed in all other tables (Tables III, IV, VI, and VII) was performed by means of (1) a modification of Fleming's micro-method¹⁸† and (2) a serial dilution method similar to Kolmer's¹⁹ employing the *Staphylococcus aureus* strain 209 P as the test organism‡. A number of specimens were subjected to parallel tests by either method, as indicated in the tables by two figures representing one specimen.

Streptomycin in the urine was determined according to the method of the Food and Drug Administration²⁰•

RESULTS

Absorption of penicillin from a suppository was prompt and rapid (Table I), the highest blood level in every case was found in the first blood specimen taken, the fifteen-minute level, whenever obtained, exceeded the half-hour reading which in turn was invariably higher than the result of the one-hour sample. Most significant in this connection was the occurrence (Case 5) of sudden diarrhea ten minutes after the suppository was inserted, the blood titer five minutes thereafter, as well as the penicillin excretion in the six-hour urine specimen, compared well with the respective findings in other trials in which no such loss was observed. Penicillin activity of the serum was still well assayable after six hours whenever determined in Cases 1 to 11, and after nine hours in Cases 8 and 11 (two subjects receiving high dosage). In all instances in which fractional urine samples were examined, the quantity of penicillin excreted in the first three hours exceeded the amount found in the following nine hours and amounted in most cases to more than 50 per cent of the twenty-four hour recovery. The latter ranged between 3.6 and 8.3 per cent, a mean percentage recovery of 6.3.

*These assays were carried out at the Venereal Disease Research Laboratories, U. S. Marine Hospital, Staten Island, N. Y.

The rectal application of streptomycin preceding the insertion of a penicillin suppository (Table I, Cases 12 to 15) caused an apparent lowering of penicillin values in both blood and urine. This fact is particularly obvious when the results in Cases 12 to 14 are compared with those obtained in the same patients without the use of streptomycin (Cases 2 to 4). After three hours penicillin activity of the blood was at or below the sensitivity limit of the test organism.

In all urine specimens collected in Cases 12 to 15 the streptomycin content was either minute (Case 14) or not demonstrable, a result expected from investigations of oral ingestion.¹

In the retention enema group (Table II) penicillin activity in the serum tested in each case in as many samples as in the suppository series was found to be either very low (maximum was 0.05 unit per milliliter at six hours in Case 4) or not assailable at all. Also the total urinary recovery was generally less in the saline group. The quantity of penicillin excreted during the first collection period was usually smaller than in the subsequent sample in contrast to the predominantly inverse ratio in the former series.

The findings in cases treated with cocoa butter capsules (Table III) were in part similar to those experienced in the suppository trials with early peaks of the blood levels and a penicillin excretion predominant within the first few

§Six-year-old boy weighing 45 pounds

hours. The excretion ratio of 26.2 per cent in Case 4, where defecation occurred ten minutes after insertion of the capsule, deserves special attention. The greater height of the serum levels and the average urinary recovery ratio of about 25 per cent make this method far superior to the simple suppositories.

With the use of rectal gelatin capsules* (Tables IV and V), the urinary penicillin excretion was generally lower and within a much wider range, allowing no mean value to be computed. The serum concentrations likewise were lower than those shown in Table III. The half-hour readings in Cases 1 and 4 were higher than those of the earlier levels, and later urine specimens often contained more penicillin than the first three hour collections, suggesting a relative delay in absorption.

In the insufflation experiments, the actual amount of penicillin reaching and adhering to the mucosa was surely less than the quantity obtained from the commercial vials, since diffusion of some of the powder over the inner surface of the instrument and over the examiner's face and clothing was noted following every such procedure. Therefore, the true absorption ratio for the penicillin which remained in the rectum is undoubtedly better than appears from Table VI. Still, most results here are comparable with those found with cocoa butter

capsules in regard to both speed and degree of systemic uptake. The presence of much fecal matter (Cases 1 and 3) did not seem to interfere noticeably with absorption.

DISCUSSION

Rectal absorption from a penicillin solution is more erratic and less prompt and efficient than from a suppository or cocoa butter capsule containing the drug. The reason for this could be passage of enemas into the proximal portions of the colon²² with more limited absorption capacity and exposure of penicillin in the aqueous medium to bacterial penicillinase action. On the other hand, a suppository or capsule remains in the lower rectum just above the sphincters where absorption is enhanced by the hemorrhoidal venous plexus with its portal and caval communications²³, besides, penicillinase activity is unlikely in an oily medium²⁴. This distinction in absorption between penicillin suppositories and enemas appears both to confirm and explain the contradictory experimental reports referred to.

The rapid initial absorption from a simple suppository associated with a relatively low blood level and urinary excretion, when first observed, indicated a retention in the rectum of most of the drug. The early descent of the blood level was probably not due to penicillinase interference, since it takes several hours to record in *in vitro* emulsions of stools with penicillin a marked loss of antibiotic activity.⁶ Moreover, the streptomycin suppositories given in order to combat colon bacillus activity and to increase penicillin absorption were found to depress the latter (Table I). These facts pointed to the accumulation in the rectum of the oily material and to its intimate contact with penicillin as important interfering factors. The experiments with insufflation and with cocoa butter capsules, containing the vehicle in smaller quantity and unmixed with the antibiotic, seem to have borne out these conclusions, the efficiency of absorption here is about fourfold.

The mostly disappointing results with gelatin capsules may be accounted for by slow or incomplete disintegration of gelatin and/or by possible adsorption of penicillin to the dissolved gelatin or to the lubricant used in some instances.

The insufflation experiments, inaccurate as they may be, suggest that absorption from pure dry penicillin applied directly to the rectal mucosa is prompt and therapeutically significant. No noteworthy local irritation was observed in these or in any other of the experiments reported.

The type of penicillin used, as indicated in the tables, does not seem to have had a noticeable bearing on the results.

The accuracy of all the findings tabulated, save for the saline group, is impaired by the inevitable loss of penicillin incurred in the preparation of the various suppositories and capsules, estimated at 5 to 10 per cent. Dosages as listed in the tables are, of course, copied from the labels of the vials from which the drug was obtained. The true serum and excretion values, therefore, in each such experiment must be regarded as somewhat higher than tabulated. Needless to say, the error inherent in the methods of bio-assay employed is considerable (± 20 per cent).

In any case, the average excretion ratio of penicillin applied rectally either by insufflation or in cocoa butter capsules appears to amount to no less than one fifth of the absorption coefficient of injected penicillin (Table VII), which ranges between 60 and 100 per cent.⁷⁻⁹ Thus the rectal route is not inferior to the oral route which produces an average penicillin absorption of 20 per cent.^{6-7, 28} This is also evident from a comparison of the results of oral administration (Table VII, Case 2) with those of rectal administration (Table III, Case 5) in the same child. With the other methods of application tested the absorption ratio is lower. The usual rapidity of absorption from the cocoa butter preparations seems to rule out any significant interference by bacterial action. Further trials with different menstrua and improvement in the manufacture of suppositories it is hoped will reveal an even greater efficiency of penicillin absorption from the rectum and make it a useful means of systemic administration.

SUMMARY

The absorption ratio of penicillin from the rectum is chiefly determined by the method of administration. It is very low after microclysters of penicillin solution, about 6 per cent in the case of cocoa butter suppositories, and subject to wide variations with gelatin capsules. Absorption of penicillin in insufflated or applied in cocoa butter capsules into the rectum is equivalent to upper intestinal absorption. The clinical use of the rectal route seems to depend upon ultimate selection of the most suitable vehicle.

PARENTERAL NUTRITION

III STUDIES ON THE TOLERANCE OF DOGS TO INTRAVENOUS ADMINISTRATION OF FAT EMULSIONS

HARVEY S. COLLINS, M.D., LISBETH M. KRAFT, D.V.M., THOMAS D. KINNEY, M.D.,
CHARLES S. DAVIDSON, M.D., JOHN YOUNG, M.D. AND FREDRICK J. STARR, M.D.
BOSTON, MASS.

PREVIOUS work in this laboratory has dealt with the problem of fat emulsions suitable for intravenous administration^{1,2}. The desirability of fat as a part of parenteral nutrition is evident as a means of securing a high caloric intake with a minimum of fluid volume. With a sufficiently high caloric intake the utilization of protein from parenteral sources would be maximal, the destruction of body protein as a result of a caloric deficit would be minimal and it ought to be possible to improve considerably the nutritional status of a severely emaciated child or adult. That emulsions given intravenously are utilized has been shown in the dog by gain in weight by total carcass analysis for fat and by change from negative to positive nitrogen balance by increasing only calories as a result of intravenous fat³.

In the studies previously reported, a 15 per cent fat emulsion was infused into dogs at a slow rate. Granulomatous lesions were found principally in the lungs and spleen and to a less extent in the liver after daily infusion for thirty to ninety days. The fat emulsion contained in addition to fat a soybean phosphatide preparation as a stabilizing agent; this material may have been primarily responsible for these histopathologic lesions. The purpose of the present study is to report observations on the following: the tolerance of dogs to emulsions of 30 per cent fat and to the rapid administration intravenously of such emulsions; the length of time infused fat remains in the blood; and whether the fat or the stabilizer is primarily responsible for the granulomatous lesions.

EXPERIMENTAL

A total of sixteen adult mongrel dogs was used in these studies. The fat emulsions were infused into the leg veins as usual. The preparation of the fat emulsions was similar to that previously used and the composition is given in Table I. Total plasma fatty acids were determined by the method of Bloor. The hematologic studies were made by the usual techniques, and the determinations of biomsulfalein elimination, plasma phosphatase and plasma cholesterol components were as previously described⁵. In spite of an epidemic of distemper which developed while the experiments were in progress the fat infusions were

Received for publication Nov. 10, 1947.

weight loss occurred during this second period of fat infusion which was similar to the first period in the emulsion used, the total amount of fat given, the rate at which it was given, and the number of days the animal was infused. Indeed, there was a gain in weight of 1.4 kilograms. The dog appeared perfectly normal at the end of the experiment. Biomsulfalein tests done periodically throughout the complete experiment (sixty-six days, see Fig. 1) suggested at times a moderate impairment of liver function as previously noted,³ but results frequently were normal.

At post-mortem examination this animal (Dog 50) showed granulomatous lesions in the lungs which were similar to those described previously.^{2, 3} These consisted of small nodules of two or three giant cells surrounded by round cells. There were also several larger collections of round cells and polymorphonuclear leucocytes that were not associated with giant cells. Small collections of macrophages with yellow pigment were in the alveoli. Large collections of polymorphonuclear leucocytes were seen in the portal areas of the liver but without granulomatous lesions or fatty metamorphosis. There were collections of round cells in the kidney and several large nodules of lymphoid and plasma cells and fibroblasts. No giant cells were observed. The heart, spleen, gastrointestinal tract, pancreas, adrenals, lymph nodes, blood vessels, and brain were normal.

Sections of the lungs of the other dogs of Experiment 1 that were alive at the completion of the experiment showed approximately four relatively small granulomatous lesions per low-power field. The livers of Dogs 52 and 48 showed polymorphonuclear leucocytes in the portal areas. There was no fatty metamorphosis of the liver in any of the animals. There was yellowish-brown pigment in the spleen and lymph nodes. The other organs were normal.

Experiment 2—The object of this experiment was to determine whether the fat or the phosphatide was principally responsible for the granulomatous lesions that had been observed following infusion of fat emulsions. In this experiment a total of six dogs was used. They were divided into three groups of two each and for the first two weeks of the study were fed horse meat and dog chow ad libitum though food consumption records were kept. During the next two weeks the amount of horse meat and dog chow fed daily was arbitrarily cut to half the average daily amount of the first two-week period. At the beginning of the third period (twenty-ninth day of experiment) all the dogs received intravenous infusions in addition to the amount of horse meat and dog chow given in the second period with the reduced rations. One group received Emulsion 11M (15 per cent fat), the second group, Emulsion 13 (2 per cent fat), and the third group, Emulsion 14 (no added fat). These infusions were given daily for the next thirty-two days in the amount of 12 to 14 ml per kilogram body weight per day and in a period of twenty minutes. The experiment was terminated on the sixty-first day for one of the dogs receiving the 15 per cent emulsion and for both of the dogs receiving the 2 per cent emulsion. The remaining three animals were infused for forty more days, though the two dogs that had received Emulsion 14 without any added fat were permitted ad libitum oral feeding. Since the response in weight for the animals in each group was similar, only one weight curve for each group is given, these are in Fig. 2. Hematologic and chemical data obtained on these dogs are given in Table III.

Fat tolerance curves At various times throughout the fat infusion periods of the two dogs receiving the 15 per cent fat emulsion (Dogs 58 and 50) in Experiment 2, a number of fat tolerance studies were made. These consisted of determining the total plasma fatty acids immediately before the infusion and at varying intervals during and after. Two typical curves are shown in Fig 3.

Post-mortem examination All the dogs of Experiment 2 were autopsied at the termination of the experiment. The dogs that received either the 15 per cent or the 2 per cent fat emulsion showed essentially similar pathologic changes.

Fig 3—Fat tolerance curves in dogs following infusion of 15 per cent fat Emulsion 11 M in Experiment 2

Granulomatous lesions in the lungs were fewer and less severe than those found in the lungs of the animals in Experiment 1 and also less severe and less numerous than those found in any of the animals which we have previously studied. All of the four animals had evidence of distemper. No granulomatous lesions were found in any of the other organs.

Dogs 59 and 63 given the soy bean phosphatide alone, are of particular interest. More severe and more numerous granulomatous lesions were found in the lungs of these dogs. Foreign body giant cells were strikingly prominent in these lesions and particulate matter was identified in many of these cells.

Experiment 3—In this experiment a pregnant dog was given daily fat infusions. The dog was fed ad libitum a purified low fat ration (compare with ration 2, reference 3) during the first two week period. Food consumption records were kept and during the second two week period half the average daily consumption of the first period was given. At the beginning of the third period (twenty-ninth day of the experiment) daily fat infusions with Emulsion 11M (15 per cent fat) were started in addition to continuing the purified oral ration in the amount used in the preceding two week period. An arbitrary amount of 300 ml of fat emulsion was given daily. This furnished 460 calories, or an average of 33 calories per kilo of body weight. The quantity of purified ration fed amounted to 80 Gm per day and furnished 309 calories, or an average of 22 per kilo of body weight. The fat infusions and purified ration were continued daily until the day the pups were born. They were not given on the day of delivery.

on the day following but then were given as previously for a further period of thirty five days after which they were discontinued and ad libitum feeding of dog chow and horse meat continued for the rest of the experiment. On the day of delivery, milk, meat, and dog chow were fed ad libitum. A lobectomy was

Fig 4—Weight curve for Dog 6 Experiment 3 fat infusion during pregnancy

done on this animal eighty eight days after delivery which was fifty two days after the last fat infusion. Weight and hematologic records were kept for an additional seventy five days after which the animal was sacrificed for post mortem examinations. The weight curve of this animal is given in Fig 4 and the chemical and hematologic data in Table IV.

Total plasma fatty acids milligrams per cent

Post-mortem examination of this dog revealed no unusual findings grossly. Microscopic examination of the lobe of the lung removed surgically showed approximately one granulomatous lesion per two low power fields. The lesions were smaller and less numerous than those generally found. The lungs at autopsy showed even fewer granulomatous lesions, approximately one per ten low power fields. These lesions were even smaller than those seen in the lobe removed sur-

gically and there was very little scar formation. There was a fairly large area in the myocardium infiltrated with round cells and polymorphonuclear leucocytes. The liver showed focal areas of necrosis in the portal areas but no granulomatous lesions or fatty metamorphosis. There was hyperplasia of both the red and white series of the bone marrow. The spleen, gastrointestinal tract, pancreas, adrenal, lymph nodes, blood vessels, and brain were normal.

The autopsy on this dog was performed seventy-five days following the surgical removal of the lung and one hundred twenty-seven days after the last injection of fat. It is apparent from these findings that the lesions described tended to regress slowly, for there was a striking difference in the number and size of the lesions in the lung removed surgically and the lungs examined at the time of autopsy.

DISCUSSION

The studies in Experiment 1 demonstrate that fat can be given in an emulsion at least twice as concentrated as we had previously used (30 per cent as compared with 15 per cent) and at a much more rapid rate. These observations are of importance in the potential clinical use of fat emulsions because they indicate that a considerable number of calories in a limited fluid volume may be given in a relatively short time, thus eliminating a considerable increase in blood volume and prolonged periods of intravenous infusion.

The 30 per cent fat emulsion furnishes approximately 30 calories per milliliter. The dogs tolerated the emulsion well except for the first two or three days of the infusion period when there was considerable vomiting, but even this generally could be controlled if the emulsion was given slowly, especially during the first half of the infusion period.

Dog 50 of Experiment 1 is of much interest because it had two periods of fat infusions, the total amount of fat being the same in each period and quite large, namely 770 grams. The first of these infusion periods began a few days after the dog became distemperous and for a time the infused fat constituted the sole source of calories because the dog was completely anorectic. During this period the dog rapidly lost weight, but probably less than would have been experienced had the animal not been receiving fat. During the second infusion period, identical to the first except that the dog had recovered from distemper, the fat was well tolerated, weight gain was rapid, and the dog was in excellent condition at the end of the experiment.

In Experiment 2 a preliminary attempt was made to find out whether the fat or the phosphatide used as the stabilizing agent was principally responsible for the granulomatous lesions that had always been observed following infusion. For this reason, infusions of a 15 per cent fat emulsion, a 2 per cent fat emulsion, and an emulsion containing no added fat but simply the phosphatide preparation were made. Two dogs were given each preparation for varying periods of time as indicated in Table III. The histopathology produced in all of these animals was essentially the same but was more accentuated in the two dogs receiving the phosphatide alone. It appears that the phosphatide preparation is the basic cause of the granulomatous lesions we have observed.

The hematologic and chemical data obtained in the six dogs in Experiment 2 (Table III) reveal a consistent decline in the hemoglobin and hematocrit throughout the course of the infusions. With the exception of Dog 63, which was one of the animals receiving only the phosphatides this change was essentially the same in all animals and was not dependent on the amount of fat in the emulsion. In none of the dogs was there any significant reticulocytosis suggesting that the anemia was not hemolytic. Bromsulfalein elimination in all dogs and plasma total cholesterol and cholesterol esters varied from normal to values somewhat higher. Plasma phosphatase values showed a definite increase throughout the infusion periods in all dogs except Dog 63.

Total plasma fatty acids values in the dog generally range from 200 to 450 mg per cent, depending principally on the diet and the time interval after eating that blood is taken for analysis. As the fat tolerance curves in Fig 3 show, there is a rapid rise in plasma fat following infusion of a fat emulsion to a value approximately twice the normal. As soon as the infusion is finished the plasma fat begins to decrease and in the short time of approximately one hour is back to normal. It is evident that infused fat leaves the blood stream rapidly.

While Experiment 3 consists of observations on only one dog, it is of particular interest in that it presents the results of fat infusion in a dog throughout the last half of pregnancy. The average oral intake of this animal was decreased during the second two weeks of the experiment to one half the amount consumed during the first two week period. From Fig 3 it is seen that during the second two-week period there was a progressive weight loss totaling 2 kilograms. This weight loss was stopped at the end of the second two week period when infusions with the 15 per cent fat emulsion were started. These infusions furnished an additional 460 calories per day or 33 calories per kilo of body weight. The infusions were given daily beginning with the twenty-ninth experimental day, except on the day of whelping and the day immediately following. They were discontinued on the ninety-eighth experimental day. There were only two pups in the litter and they were small and scrawny, however both lived and developed into healthy dogs. The mother had no difficulty in feeding them.

A lobectomy was done fifty-two days after the last of 120 daily fat infusions. The animal was sacrificed seventy-four days following the lobectomy which was the two hundred and twenty-fourth experimental day. At the end of the experiment the animal had completely made up all weight loss. Hemoglobin and hematocrit values at the end of the study were essentially the same as at the beginning though throughout the course of the experiment both had fallen due no doubt to the combined effects of pregnancy and the daily infusions. Bromsulfalein clearance, cholesterol values (both total and esterified), plasma fat and plasma phosphatase remained essentially normal except for the values obtained just prior to whelping when they were all increased as is shown in Fig 3.

SUMMARY

1. A 30 per cent fat emulsion stabilized with soybean phosphatides (Asolectin) was given intravenously to dogs with the same ease as the 15 per cent emulsions used in our previous studies.

2 Fat emulsions can be given relatively rapidly to adult dogs

3 Fat infused into the blood stream caused a prompt and marked increase in plasma fat but normal values were approached in the adult dog within an hour after the termination of the infusion

4 It appears that the soybean phosphatide used as the stabilizer was primarily responsible for the granulomatous lesions we have observed following the use of intravenous fat emulsions

We desire to express our appreciation to Miss Virginia Kent and to Miss Mary Maloney for technical assistance

PARENTERAL NUTRITION

IV IMPROVED TECHNIQUES FOR THE PREPARATION OF FAT EMULSIONS FOR INTRAVENOUS NUTRITION

ROBERT P. GEYER, PH.D., GEORGE V. MANN, M.D. AND FREDERICK J. STARE, M.D.
BOSTON, MASS.

IN PREVIOUS reports from this laboratory^{1,2} the use of fat emulsions for the intravenous nutrition of dogs has been described. One phase of the continuation of this problem has been the improvement of techniques for preparing emulsions of suitable particle size and stability. Since the relationship of particle size to such problems as fat embolism and fat utilization is not clearly understood at present, it seems desirable that all particles in such emulsions be no larger than normal chylomicra. When particles of this magnitude are dealt with, an accurate method of measuring particle size becomes of importance. In addition, there are the usual problems met with in intravenous nutrition that is the elimination of pyrogens, sterilization, and the prevention of pathologic changes resulting from the administration of the material under study. The present paper deals with a photomicrographic method for determining particle size, a method for preparing fat emulsions whose maximum particle size is under $2\ \mu$ in diameter, and some of the preliminary studies on the physical stability of these emulsions.

EXPERIMENTAL

Photomicrographic Method for Determining the Size of Fat Particles— Quantitative measurements of fat particles below $5\ \mu$ are difficult because of Brownian movement and low optical density. Since visual determinations are only approximate a photomicrographic method was developed. In preliminary work both a tungsten filament and a carbon arc lamp were used as light sources but were not found satisfactory at high shutter speeds. Subsequently a high speed high intensity, discharge lamp was found to be adequate. The apparatus is shown in Fig. 1. An Eastman precision enlarger No. 1 with a 35 mm. film roll adapter and holder was used without a shutter or lens but was provided with a bellows adapter for the microscope. A Spencer research model microscope with an apochromatic lens system was used. Eastman Kodak Plus X'' 35 mm. roll film is satisfactory and considerably more convenient than Kodak M plates of Type B panchromatic sensitivity.

The light source consisted of an Edgerton type, high voltage discharge lamp housed in a Spencer model 370 microscope lamp.* The lamp had a discharge

Fig 1—A photograph of the equipment used in preparing photomicrographs of emulsions

time of $\frac{1}{50,000}$ second. Focusing of the microscope was accomplished by means of a General Electric 100 watt projection type tungsten filament bulb contained in the aluminum holder shown in Fig 1. The focusing lamp assembly was previously centered with respect to the optical axis of the flash lamp. After focusing, the holder was removed from its position atop the discharge lamp casing.

In practice, a thin sample of undiluted emulsion was placed between a slide and cover slip and the chamber sealed with paraffin to prevent evaporation. For examination of a preparation the sample was removed from the surface, since the largest particles in the preparation tend to accumulate there. For some purposes sampling with a pipette and bulb at varying depths from the surface was done.

Calibration was accomplished by photographing and enlarging a slide micrometer in the same manner as was used for the emulsions. Measurements were then made by means of rule and caliper.

By a series of trials it was possible to establish the proper lamp diaphragm, field stop, and bellows length settings which would produce optimum results. Since the intensity and duration of the illuminating source were constant, the field stop on the lamp was used to control intensity. The substage condenser diaphragm was used to develop contrast. In general, maximal contrast was developed with the condenser diaphragm aperture reduced considerably below the numerical aperture rating of the objective used.

The combination of lens systems used was determined by the dimensional range of the material to be measured. For the emulsion particles under $2\ \mu$ the 2 mm objective with oil immersions above and below the slide and with a 10X ocular gave the best results. A Wratten B filter was interposed between the ocular and the camera as a means of further accentuating contrast. This filter transmits between 480 and 620 millimicrons. The bellows length was kept short. Additional magnification was accomplished when necessary by enlargement of the negatives.

For measurement, 3 by 5 inch enlargements of the negatives were satisfactory. Development of the negatives was designed to produce maximal contrast, and prints were made on No. 4 (Eastman) high contrast paper.

In practice each preparation measured is searched under high dry magnification for fields showing the largest particles and several of these are photographed, because maximal particle size is of prime importance. As mentioned below, in these emulsions the vast majority of the fat particles are less than 0.2 to $0.5\ \mu$ in diameter and thus beyond the resolution of the light microscope.

Fig. 2 illustrates representative photographs of three emulsions and the scale photographs used in the measurements.

Preparation of Emulsions—Several different methods of preparing fat emulsions were studied under similar conditions to determine which warranted extensive consideration. Emulsions were produced by means of (1) a Waring blender (2) a hand homogenizer (3) an ultrasonic generator* and (4) a high pressure homogenizer†. Aqueous dilution of a nonaqueous solution of fat and stabilizer was also tested. In each case the following constituents were used: coconut oil, soybean phosphatides‡ and distilled water. Since the high pressure homogenization method yielded the best emulsion from the standpoint of particle size further studies were conducted using this method of production.

After preliminary work the following general procedure was adopted for carrying out an emulsification.

Premixing of Emulsion Constituents—Double distilled water previously boiled for four minutes was placed in a Waring blender with the fractionated phosphatide preparation§. The mixture was spun at top speed for two min-

Representative photomicrographs made at the lower of a relatively coarse magnification. The scale is in microns.

utes and hot coconut oil (80 to 95° C) was slowly added while the blender was still rotating. Blending was continued for an additional three to five minutes. Throughout the entire process a flowing atmosphere of nitrogen was provided by means of a suitable attachment tube on the cover. Though the fat particles ranged from 1 to 15 μ in diameter, this degree of dispersion was sufficient temporarily to prevent excessive "oiling out" when the material was placed in the high pressure homogenizer.

High Pressure Homogenization Step—The premixed material was introduced into the operating high pressure homogenizer which was equipped with the external glass recirculating system shown in Fig 3. The homogenizer was a smaller model of the machine used by McKibbin and co workers and was better adapted for small volumes of material. Prior to the addition of the blended emulsion, the machine was freed of water by operating with the pressure regu-

Fig 3—Diagram of high pressure homogenizing apparatus used in preparing fat emulsions for intravenous nutrition

lator block and the external port opened. By means of a long stiff wire bent in a right angle near one end the suction valves were lifted to allow the water in the middle chamber to drain. After all parts were again replaced and tightened the machine was run while nitrogen was supplied to displace the air. When the blended material had been added, the thermometer was put in place and the flow of nitrogen was adjusted to a very slow rate. Where required, heat was supplied by regulating the flow of hot water (76° C) through tube A (Fig 3). In those cases where a low temperature was desired the temperature of this water was lowered. In operation the condenser water flowed slowly

over the piston rods through an appropriately placed three-holed length of copper tubing (*B*). This made it unnecessary to use the cooling system provided by the manufacturer and insured better control of the temperature of the equipment and homogenate. To remove trapped gas, the machine was run at zero pressure and the rubber tube (*D*) was alternately closed and opened. If this was unsuccessful the pressure was raised to 2,200 pounds and maintained until the temperature of the circulating homogenate reached 75 to 78° C, at which point the gas either escaped or could be removed by closing the rubber tube.

Preliminary investigation demonstrated that although many particles below 1 μ were formed by single passage of the material through the homogenizer, some particles as large as 6 to 8 μ remained even after ten to fifteen passages at pressure between 2,000 and 4,000 pounds per square inch. For this reason the material was continuously recycled through the apparatus for periods of time ranging up to ninety minutes.

To determine the effect of temperature upon the rate of emulsification a series of tests were made using Emulsion 22 at 41, 60, 76, and 85° C. (For composition of Emulsion 22 see Table II.) The premixing in each case was done as described previously. It was found necessary to run cold water over the block to maintain the lowest temperature. Samples were removed at ten, twenty, and thirty-five minutes, and the size of the largest particles was ascertained. Table I contains the results of these tests carried out at a pressure of 3,000 pounds per square inch.

TABLE I EFFECT OF TEMPERATURE ON THE RATE OF EMULSIFICATION
(VOLUME, 500 C C, PRESSURE, 3,000 POUNDS PER SQUARE INCH)

EXPERIMENT	TEMPERATURE (°C)	APPROXIMATE DIAMETER IN MICRA OF LARGEST PARTICLES OF A 30% FAT EMULSION (EMULSION 22)		
		10 MIN	20 MIN	35 MIN
1	41	8-10	4-6	<3
2	60	5-7	4-6	<3
3	76	4-6	2-4	<2
4	85	4-6	3	<1

The effect of pressure was studied by preparing 500 c c quantities of Emulsion 31 at 2000, 2500, 3000, 3500, 4000, and 4500 pounds per square inch respectively. (For composition of Emulsion 31 see Table II.) Homogenization was carried out for thirty to forty-five minutes at 76 to 80° C. Visual microscopic examination of samples removed at ten-minute intervals was used as a criterion. It was found that although all pressures used resulted in particles below 2 μ , the pressures above 3,000 pounds per square inch resulted in a greater proportion of the particles being at the extreme end of microscopic resolution. Thus emulsions prepared at higher pressures could be viewed microscopically when undiluted, without having the field of vision limited to the upper layers of the preparation. The emulsions appeared blue by reflected light in thin films and appeared red by transmitted light. These phenomena were observed with emulsions containing both 15 and 30 per cent of fat.

A number of emulsions were prepared in an investigation of the levels and ratios of fat and phosphatide conducive to small particle formation and stability. The amount of phosphatide was varied between 0.15 and 6.0 Gm per 100 cc, and the fat, between 10 and 30 Gm per 100 cubic centimeters. The fat was either coconut oil, corn oil or butter fat*. The emulsions prepared and the data pertaining to the conditions of preparation are given in Table II. Also included are the size of the particles produced and the effect of autoclaving for fifteen minutes at 15 pounds per square inch.

Fat emulsions are adversely affected by high electrolyte concentration, low pH (below 6.0), prolonged heating, evaporation of the water phase, and the presence of materials which carry electric charges dissimilar to those of the fat particles. Many of the emulsions given in Table II were studied under these adverse conditions. These studies are still in progress and will be reported in full at a later date. It is clear that for a high fat level more emulsifier is required for stability under adverse conditions. In addition it has been found that, with a given level of emulsifier, as the concentration of oil increases the emulsions are formed with increasing difficulty. It also has been found that small particles are of prime importance to stability. Thus emulsions whose particles of fat are less than $2\ \mu$ in diameter and have a probable mean diameter below $0.5\ \mu$ are completely stable to autoclaving, whereas, otherwise comparable emulsions containing many particles above $5\ \mu$ either break or cream out under the treatment or upon standing.

Emulsions similar to Emulsions 22 and 31 have been used for extensive animal investigation because they are stable and are compatible with blood both in vitro and in vivo studies. However as described in the following paper the soybean phosphatide preparation has been fractionated so as to give a more desirable stabilizing fraction, and this fraction (BF2) is used in place of the Asolectin. In routine practice the emulsions are autoclaved in gas tight bottles filled with nitrogen and with an aqueous dextrose concentration of 5 per cent. The bottles are stored in the dark at 24°C and before intravenous use 1 cc of sterile 10 per cent Na_2HPO_4 is added to each 100 cc of emulsion. The pH of the emulsion is thus brought to 7.4. The results of the in vivo studies with these emulsions will be reported at a later date.

DISCUSSION

The photomicrographic technique has furnished a means of objectively evaluating emulsion preparations. It should be emphasized that the maximum particle size is the most important single factor in determining physical stability and may have more physiologic significance than simply assuring passage through the capillaries without embolization.

Under the proper conditions high pressure homogenization resulted in the formation of fat emulsions whose largest particles were below $2\ \mu$ in diameter.

*The butter fat was prepared by melting unsalted butter at 65°C , decanting the oil portion from the curd and water and shaking with anhydrous Na_2SO_4 while warm. The fat was then filtered through a Buchner funnel using quantitative paper. The product was entirely clear. The butter was furnished through the courtesy of the H. P. Hood and Sons Co. Boston, Mass.

Of primary importance was the continuous recirculation of the material through the machine for periods of time ranging from thirty to ninety minutes, depending upon the fat content. Shorter time intervals were inadequate and also negated the advantage of using high pressures. Thus, periods of five to ten minutes yielded no better emulsions at pressures above 3 000 pounds per square inch than were obtained at 2 000 pounds per square inch. Pressures above 3,000 pounds per square inch, however, when used for longer periods of time resulted in a shift in the mean particle size toward the lower limit of visual microscopy. Such emulsions took on a bluish appearance and transmitted red light even when the fat content was as high as 30 per cent. Light field microscopic examination of a thin layer of an undiluted 15 or 30 per cent fat emulsion revealed relatively few discernible particles. Dark field examination disclosed many additional particles below 0.5μ in diameter. These characteristics indicated that most of the emulsion was a true colloidal suspension of fat in water.

The data in Table I show that high temperature was conducive to better and more rapid emulsification. When the homogenization was carried out at pressures above 3 000 pounds per square inch, the temperature rose to the boiling point provided no cooling water was used. This circumstance was helpful for both a high pressure and a high temperature were obtained simultaneously. Experience has shown that boiling may cause the emulsion to break to a certain extent probably due to loss of the water phase by surface evaporation. The beneficial effect of higher temperatures is believed to be due to lowered viscosity which permits a smaller valve opening at any given pressure, lowered interfacial tension and a decrease in the force necessary to shear the fat globules.

The levels of emulsifier and fat and the ratio between them were also found to be of great importance. In general the lower the fat level the shorter the length of time necessary for complete emulsification and the more stable the finished emulsion to high electrolyte concentration and to autoclaving and storage. Thus, a 15 per cent coconut oil 3 per cent phosphatide emulsion (Emulsion 31) was prepared in thirty minutes and was unaffected by autoclaving. Emulsion 22 which contained 30 per cent coconut oil and 3 per cent phosphatide required sixty five minutes of homogenization but was stable to autoclaving. Raising the level of stabilizer to 6 per cent made little difference in the homogenizing time required to produce a good emulsion and one stable to autoclaving. Emulsions containing 0.15 per cent phosphatide were stable to autoclaving when the fat concentration was below 15 per cent. Such emulsions, however, were broken by low electrolyte concentrations.

Added dextrose has proved satisfactory as a means of rendering the emulsions compatible with blood from the standpoint of tonicity and does not adversely affect the emulsion during autoclaving. Dextrose has the added advantage of contributing to the total caloric content. Extensive animal testing has been conducted using an emulsion similar to Emulsion 22. The composition and caloric content of Emulsion 22 is given in Table III.

TABLE III COMPOSITION AND CALORIC CONTENT OF FAT EMULSION 22

COMPONENTS	GRAMS	CALORIES
Oil	300	2700
Dextrose	35	140
Phosphatide emulsifier	50	210 (approx)
Water	634	-
Total		3050

Studies are in progress on the chemical and physical stabilities of these emulsions and on their pyrogenic properties. Also being investigated are possible costabilizers and other emulsifiers. A serious criticism of many surface active substances studied is the tendency to *in vitro* hemolysis even in the low concentrations necessary. The use of filtration through bacterial filters is being studied. It has been found that 30 per cent fat emulsions can be passed through filtering candles or pads without adversely affecting stability.

The use of high frequency sound waves as a means of emulsification has been studied by other workers.⁶ The magnetostriuctive principle is used extensively in the dairy industry in the production of homogenized milk. Our studies with sonation were not extensive but using this procedure we were unable to make emulsions which were as satisfactory for our purpose as emulsions made by a pressure homogenizer. This failure to produce good emulsions by sonation seemed to be related to two factors: first, the material could not be circulated adequately through the effective field of high-intensity cavitation, and second, the intensity of the mechanical activity of the vibrating membrane was so great that appreciable amounts of metal were dispersed into the solution.

SUMMARY

A photomicrographic apparatus and method have been developed to allow accurate determination of the size of fat particles in emulsions.

By means of high-pressure homogenization fat emulsions were prepared in which all particles were below $2\ \mu$ in diameter and most were beyond the resolving power of the light microscope.

Factors conducive to the preparation of such emulsions were high pressure, high temperature, continuous recirculation of the material being homogenized, and the proper fat-stabilizer ratio. Data on each of these are given.

PARENTERAL NUTRITION

V STUDIES ON SOYBEAN PHOSPHATIDES AS EMULSIFIERS FOR INTRAVENOUS FAT EMULSIONS

ROBERT P GEYER, PH D, GEORGE V MANN, MD JOHN YOUNG, MD
THOMAS D KINNEY, MD AND FREDRICK J STARE, MD
BOSTON, MASS

THIS laboratory has carried on research in an effort to develop fat emulsions suitable for parenteral nutrition^{1,2} Previous reports have shown that fat emulsions given intravenously to dogs can be utilized as a source of energy, that dogs are able to handle large quantities of emulsified fat administered daily for long periods of time that the fat can be given in a concentration as high as 30 per cent and at a rapid rate and that the infused fat leaves the blood in a few hours However, in all the animals previously studied granulomatous lesions and scarring of the lungs, liver and spleen were noted in varying degree Preliminary observations pointed to the phosphatide preparation used as an emulsifier as the principal agent responsible for these lesions³

Since the lesions were produced by a soybean phosphatide preparation (Asolectin)* alone and since this emulsifier appeared to be the best of a large number studied it was desirable to investigate it further In all of the previous studies on this problem adult dogs had been used as the experimental animal It would be advantageous to use a smaller laboratory animal for much of this work The purpose of this paper is to report a chemical fractionation of the soybean phosphatide preparation which yields an emulsifying agent which will not give rise to the histopathology previously observed and to report observations on an improved fat emulsion given intravenously to adult rats and to puppies

EXPERIMENTAL

The plan of the first part of this study was to utilize the rat as an experimental animal to assay various fractions of the phosphatide preparation both alone and as part of the fat emulsion for any lesion producing properties Both Sherman and Hisaw strains of the albino rat were used The animals weighed from 150 to 250 grams and were approximately 3 months old In most experiments a group of six rats plus controls were used Each experimental animal was given a daily injection of the material to be tested for six successive days The animals were injected through a tail vein while under light ether anesthesia The volume injected varied from 15 to 25 ml but in all cases amounted to 1 ml per 100 Gm of body weight It was given in

thirty seconds or less. Six days following the last injection (unless otherwise noted) the animals were sacrificed by etherization and bleeding. Sections of all organs were fixed in 10 per cent formalin solution, embedded in paraffin, and stained with hematoxylin-eosin. Frozen sections of formalin-fixed materials were stained for fat with Sudan III when indicated.

The various fractions studied consisted of the so-called purified soybean phosphatide preparation (Asolectin) used in our previous studies and derivatives of this material obtained by fractionation procedures. These were observed for lesion-producing properties when injected alone and as a component of fat emulsions. The materials were prepared for intravenous ad-

ministration using one of the following procedures. (1) Homogenized preparations were made by the method recently described for the preparation of fat emulsions.^{*} The material was added to boiling water and spun for three minutes in a Waring blender at top speed. It was then homogenized in a high-pressure homogenizer[†] for thirty-five minutes. The pressure was maintained at 3,000 pounds per square inch, and the temperature, at 75 to 80° C. The process was carried out under a nitrogen atmosphere. Solutions were buffered with phosphate to a pH of 7.4 and made isotonic with either glucose or sodium chloride. The material was placed in brown glass pressure bottles, the air was displaced with nitrogen, and the tightly capped bottle was autoclaved at 15 pounds per square inch for fifteen minutes. (2) Blended preparations were obtained in the same manner except that the

high-pressure homogenization was omitted (3) Crudely mixed preparations were made by adding the material to water (50° C) and spinning in the blender at high speed for thirty seconds. Toxicity and sterility were achieved as with the homogenized preparations.

In the experiments to be described the pathologic lesions were restricted to the lung and were not evident grossly. On microscopic examination the most severe lesions were granulomatous in type (Fig 1). The individual lesions consisted of groups of mononuclear cells and fibroblasts with one to four giant cells of the Langerhans type at the center. In the larger nodules Mallory's aniline blue stain demonstrated loose, fine, collagenous fibers arranged in concentric fashion. Seen among the fibers were large epithelioid cells. A few of the larger lesions had necrotic centers with many polymorphonuclear leucocytes. The giant cells contained from a few to twenty or thirty nuclei. These were arranged about the periphery of an abundant amount of light basophilic to eosinophilic cytoplasm. The cytoplasm was homogenous for the most part. However, some giant cells contained small droplets that stained red with Sudan III while in other giant cells particulate matter was seen. Refractile bodies were not observed when a frozen section of the tissue was examined through a polarizing microscope. Ziehl-Neelsen stain demonstrated no acid-fast material in the cytoplasm. No asteroid bodies were seen in the cytoplasm. The nuclei had prominent nuclear membranes and centrally placed nucleoli. The lesions in the more severe cases varied in size from 0.1 to 1.0 millimeter. In some instances the nodules were confluent. They had no constant relationship to bronchi or vessels. There was steady regression in the size of the lesions in animals which were allowed to live for a longer period than that stated.

The less severe lesions were seldom over 0.5 millimeter (Fig 2). There was little or no fibrosis and no necrosis. The nodules consisted of mononuclear cells and one to two giant cells, which were similar to those seen in the largest lesions.

Some of the lesions consisted of only one to two giant cells with no cellular elements or fibrosis about them (Fig 3). These were seen in the alveolar walls with only a separation of the basement membranes on each side.

The sections were graded according to the severity and frequency of the giant cell lesions. Four plus lesions were the most severe. In these there were three to four nodules per low-power field which were often confluent. The lesions themselves were large, with fibrosis and some necrosis. Three plus lesions were smaller with little fibrosis and no necrosis. However, they were almost as frequently seen as the four plus, occurring from one to three times per low-power field. Two plus lesions were small and infrequent, one lesion being observed per three high-power fields. One plus lesions consisted of rare isolated giant cells with no cellular components about them.

Rat Assay Experiments, Part I—

Experiment 1 The soybean phosphatide preparation (Asolectin) in a concentration of 3 per cent in boiling water was blended in a Waring blender for a period of ten minutes. Microscopic examination of the material showed

that the suspended particles varied from 10 to 20 μ in size. Six adult rats were injected with this material. Sections of the lungs from all the assay animals showed numerous four plus lesions. In the center of some of the lesions there was definite necrosis and infiltration by polymorphonuclear leucocytes. These lesions were more numerous and larger than those found in any of the subsequent groups. These results and those of subsequent experiments are given in Table I.

Animal died one hour following last injection

Experiment 2 The soybean phosphatide preparation (Asolectin) in a concentration of 3 per cent in water was homogenized. The particle size in this emulsion was 2 μ or smaller. A group of six rats were injected. Sections of the lungs from all animals showed small one plus lesions. There was little fibrosis or infiltration and no necrosis.

Experiment 3 The soybean phosphatide (Asolectin) in a concentration of 9 per cent in water was homogenized. It was injected into three rats daily for only two days. The animals were sacrificed on the twelfth day of the experiment. Sections of the lungs were graded one plus and were similar to the lungs of the animals in Experiment 2. This experiment was carried out to determine if the total amount of phosphatide homogenate could be given in a shorter period of time without changing the number or severity of the lesions. It was concluded that, within limits, the rate of administration of the homogenized phosphatide was not a significant factor in the production of the lesions.

Fractionation of the Phosphatide Preparation, Asolectin—While the homogenized phosphatide preparations produced relatively few lesions it was felt that further experiments should be carried out to eliminate, if possible, the factor or factors responsible for the few lesions that were present without destroying any of the emulsifying properties of the phosphatides. Consequently, several chemical fractionation procedures were done on the purified soybean phosphatide and many of these preparations were then assayed for lesion-producing properties as in the previous experiments.

Fractionation 1 (F1) One hundred grams of soybean phosphatides were dissolved in 500 cc of chloroform. To this solution 1,500 cc of acetone were added slowly, with stirring, to yield a finely divided precipitate of phosphatides. After filtration the precipitate was redissolved in 100 cc chloroform and reprecipitated with 300 cc of acetone. After filtration the solid product was washed twice with acetone and was then freed of solvent by means of vacuum at room temperature. The combined filtrates from the preceding operations were taken to dryness under vacuum in a stream of nitrogen and yielded 18.2 Gm of a dark, gummy material which was given the designation A(F1). The acetone precipitate was added to 350 cc of absolute alcohol (63° C) and was spun in a Waring blender at high speed for three minutes. The suspension was cooled to room temperature and placed in the refrigerator overnight (7° C). After filtration through a Buehner funnel, the precipitate was washed with three 30 cc portions of cold absolute alcohol. The entire alcohol treatment was repeated except that the material was filtered after seven hours. Removal of the residual solvent from the precipitate yielded 41 Gm of a granular, light-tan material which was designated B(F1). The combined filtrates from the alcohol treatment were concentrated in vacuum under nitrogen and furnished 19.4 Gm of a light-yellow, amorphous substance. This was designated C(F1). The yields of both C(F1) and B(F1) were low because of loss during the initial step of this method.

Fractionation 2 (F2) It was found that a diethyl ether solution of soybean phosphatide remained turbid. This insoluble material would have appeared in fraction B(F1) of the previous procedure. Therefore, 50 Gm of phosphatides were dissolved in 100 cc of diethyl ether and the insoluble particulate material was removed by centrifugation. This material was washed five times with 10 cc portions of diethyl ether and was then freed of solvent under vacuum. This yielded 31 mg of a white powder which was designated A(F2). Microscopically this material comprised some particles which closely resembled rod-shaped bacteria and other particles which were of many irregular shapes and which ranged in size from less than 1 micron to 15 micra. Subsequent chemical determinations demonstrated that much of this material gives color tests characteristic of denatured proteins.

The filtrate from the preceding paragraph was made up to 200 cc with diethyl ether and was placed in the refrigerator (-7° C) for forty-eight hours. A slight cloudiness developed but disappeared on warming. Fifty cubic centimeters of acetone were added and after thorough shaking the solution was

placed at -7°C overnight. The top layer was decanted and the bottom layer was carried through the diethyl ether acetone procedure again. After decantation, the top layers were combined and were concentrated under vacuum in a stream of nitrogen. The yield was 5.4 Gm of a very dark, viscous, gummy substance. This comprised preparation C(F2).

The bottom layer from the previous procedure was filtered through a Sartz filter using positive pressure. Concentration under vacuum yielded 32 Gm of a light yellow, granular material B(F2).

Rat Assay Experiments Part II—

Experiment 4 A 3 per cent suspension of fraction A(F1) was prepared by mixing in a Waring blender for three minutes with boiling water. After autoclaving this material it was injected into six adult rats daily for a period of six days. The dosage was as previously mentioned for all of these experiments. The rats were sacrificed on the twelfth day of the experiment. Sections of the lungs showed one plus lesions.

Experiment 5 A blended 3 per cent suspension of fraction C(F1) in water was injected into three rats daily for six days. The rats were sacrificed on the twelfth day of the experiment. Sections of the lungs were graded three plus for lesions. These lesions while as numerous as those found in the animals injected with blended whole phosphatide (Experiment 1) were not so large. Also, there was less inflammatory reaction and fibrosis and foreign body giant cells were less numerous per lesion.

Experiment 7 A 9.5 mg per cent suspension of fraction A(F2) in water was injected into three rats daily for six days. This material was prepared for injection by grinding in a mortar with 5 Gm of dextrose and then was taken into water. The rats were sacrificed on the twelfth day of the experiment. Sections of the lungs were graded one plus for lesions.

Experiment 8 Two groups of animals were used to test a blended preparation of fraction B(F2) in which the particle size varied from 1 to 2 micra. It was injected into six rats daily for six days. These rats were sacrificed on the twelfth experimental day. Sections of the lungs showed no lesions.

Experiment 9 In the second assay with fraction B(F2) it was again made up in 3 per cent concentration in water but was emulsified in the Waring blender. The particle size varied from 1 micron to 8 micra. This material was injected into four rats daily for six days. The animals were sacrificed on the twelfth experimental day. No lesions were found in the lungs of two rats. The remaining two rats had lesions graded one plus. These lesions were small with no fibrosis or cellulose infiltrates.

Experiment 10 Fraction C(F2) was not suitable for injection by itself because of its high content of fatty acids and neutral fats and consequent insolubility in water. For this reason blended preparations were made up as follows: the first contained fractions A(F2) plus B(F2) and the second fractions C(F2) plus B(F2) both fractions in a concentration of 1.5 per cent in water. The B(F2) preparation was thus used as an emulsifier for the insoluble

A(F2) and C(F2), and the total concentration of each combined fraction was 3 per cent. Three rats were given six daily injections of fractions C(F2) plus B(F2) and were sacrificed on the twelfth experimental day. The lungs were graded one plus. Three additional rats were given six daily injections of A(F2) and B(F2) and were killed on the twelfth experiment day. The lungs were graded two plus in one rat and three plus in the other two. There were a few medium sized lesions but the majority were small.

Experiment 11 It was felt that microorganisms growing in the crude products might be partially responsible for the production of lesions even though they were killed by autoclaving. The coconut oil, crude phosphatide, and water from the homogenizer were cultured. *Staphylococcus albus* and *Aspergillus niger* were recovered from the crude phosphatide. The fungus was grown in pure culture, suspended in isotonic saline autoclaved at 15 pounds pressure for fifteen minutes, and injected into six rats in a manner similar to that used in the other experiments. The rats were sacrificed on the twelfth day of the experiment. The lungs were graded three plus for lesions. Spores and hyphae were demonstrated in the giant cells. In this instance, lesions were also found in the spleen and liver.

Experiment 12 An emulsion (Emulsion 35)⁵ containing coconut oil, 300 Gm., phosphatide fraction B(F2), 30 Gm., dextrose, 35 Gm., and water, 634 ml., was prepared and injected daily for six days into a group of six rats. The particle size of this emulsion was less than 2 μ , predominantly less than 0.7 micron. The dosage was 0.5 cc. per 100 Gm. of body weight. The animals were sacrificed on the twelfth experimental day. Only one small lesion was found in one lung of the six rats examined.

Control Animals for Rat Assay Experiments A group of twelve rats served as controls. These animals were kept in the same cage as the experimental animals and were distributed throughout the twelve experiments. The lungs were examined and no lesions such as those described were present in any of the twelve control animals. An occasional rat in both the experimental and control groups showed pneumonitis such as is commonly encountered in laboratory rats. The lesions described herein were sufficiently characteristic to be distinguished from this type of pneumonitis.

Puppy Experiments —

Experiment 13 A more extensive study of Emulsion 35 as prepared by the improved procedure described in the previous report⁵ and using fraction B(F2) prepared from soybean phosphatides was carried out in puppies. Assay in rats had indicated that this phosphatide fraction would not lead to visceral lesions when infused as a water emulsion alone in a 3 per cent concentration or when used in that concentration as a component of a 30 per cent fat emulsion.

A group of four Labrador puppies, all littermates raised in this laboratory, was used. The animals were in apparent good health. They were wormed and during the course of the experiment were given canine distemper serum at two week intervals. Despite this precaution there were indications toward the end of the experiment that the animals were infected. Anorexia, fever, and leu

eocytosis suggested that a respiratory, bacterial infection was present. The animals were divided into two groups. The three animals in the first group were infused daily with amounts of emulsion varying from 15 to 10 Gm per kilo of body weight. The animals were fed a purified diet at the outset and were later transferred to a natural diet.* The fourth animal served as a control and was not infused.

Immediate reactions to the intravenous infusion of the emulsion were for the most part determined by the rate of the infusion. This aspect of the work and detailed metabolic studies will be reported in a later paper. Pertinent to this discussion, however, was the observation that on several occasions various dogs became dyspneic at the start of the infusion. Expiration became difficult, the animal wheezed audibly, and there were forced attempts to clear material from the trachea. In each instance auscultation revealed profuse expiratory rhonchi and wheezes. Upon discontinuation of the infusion the animal appeared well within fifteen minutes and the abnormal signs had disappeared. Examination microscopically of the emulsion involved revealed loose aggregations of particles 2 μ or less in diameter which constituted a flocculus or raft like mass measuring up to 25 μ in diameter. The nature of the conditions leading to this phenomenon is not clear. Table II presents the data concerning the number of

TABLE II. SUMMARY OF INTRAVENOUS FAT INFUSION IN PUPPIES

PUPPY	DAYS INFUSED	TOTAL EMULSION INFUSED (G)	TOTAL FAT INFUSED (GM)	TOTAL EMULSIFIER D(R2) (GM)	DAY OF EXPERIMENT SACRIFICED
904	0	0	0	0	52
907	30	2,343	703	70.3	49
905	42	4,704	1,411	141.1	56
909	84	10,295	3,089	308.9	84*

*Animal died after prolonged massive doses of emulsion leading to anorexia

days the animals were infused and the amounts of emulsion and total fat infused. Puppy 904, the control animal received no infusions, Puppy 907 received 703 Gm of fat over a thirty day period, Puppy 905 received 1,411 Gm of fat over a forty two day period and Puppy 909 received 3,089 Gm of fat over an eighty four day period. All of these puppies were sacrificed for post mortem examination at varying times as indicated in Table II. Gross examination at autopsy revealed normal appearing organs in all puppies. Sections were made of lung, liver, spleen, kidney, brain, intestine, bone marrow, adrenal and lymph nodes and were stained with hematoxylin and eosin.

Two animals (Puppies 905 and 907) were sacrificed by etherization and bleeding. Both animals had pulmonary findings consistent with a mild distemper. The lungs from both animals also showed occasional giant cell lesions which were graded one plus. No granulomatous lesions such as were described previously were found in any of the other organs. No hemosiderin deposition was noted in the spleen, liver, lymph nodes, or bone marrow. The liver was stained with Sudan III and no fat was found. There was hyperplasia of the white cell series in the bone marrow.

Gaines Dog Meal furnished through the courtesy of the Research and Development Department, General Foods Corporation, Hoboken, N. J.

Puppy 909 died during the night and all organs were markedly autolyzed. As far as could be determined there were no granulomatous lesions present. There was pulmonary edema and many of the smaller bronchi were plugged with mucous.

The control animal (Puppy 904) also showed pulmonary lesions consistent with mild distemper. No other lesions of consequence were present in any of the organs.

DISCUSSION

In previous studies^{2,4} it was shown that dogs receiving emulsions of corn oil or coconut oil in concentrations of 15 per cent, 30 per cent, or 2 per cent developed granulomatous lesions which were most marked in the lungs and more rarely found in the spleen, kidney, and liver. Essentially the same lesions were found when the emulsifying agent, a soybean phosphatide preparation, was given intravenously without added fat.⁴ In the present report it is shown that such lesions were also produced in the lungs of the albino rat under similar conditions. The liver, spleen, kidney, heart, and brain of the rats were studied but no lesions were found. The rat proved a good experimental animal for assay of the emulsions and various phosphatide fractions because only small amounts of material were required for the development of the lesions. Thus only 30 mg of the original phosphatides per 100 Gm of rat per day for a six-day period were required to produce numerous lesions. That the assay time could be reduced further is shown in Experiment 2 in which 180 mg per 100 Gm of rat given for two days also produced typical lesions. Histologic examination of the lungs seemed to provide an accurate index of the lesion-producing properties of the test materials.

The larger lesions produced in the lung were made up of mononuclear cells, fibroblasts, and foreign body giant cells. Various substances were demonstrated in some of the giant cells. Some contained neutral fat, while in others particulate matter was observed. The lesions of the rats receiving the mold showed spores and hyphae in the giant cells. In other instances small bits of leather fragments were demonstrated. The latter probably came from the leather gaskets used in the homogenizer. Preliminary experiments have suggested that by using plastic gaskets and passing the finished emulsion through a suitable filter, particulate fragments can be completely removed.

The soybean phosphatide preparation (Asolectin) used in our previous studies was fractionated to yield an emulsifying agent more suitable for intravenous use. The first fractionation of the phosphatides was unsatisfactory because the small amount of ether-insoluble material present originally was not removed prior to subsequent steps. In the second fractionation this material, fraction A(F2), was removed at the start of the procedure and consisted of particles of solid material whose greatest dimension was as large as 12 micra. Such particles would be sufficiently large to block the alveolar capillaries in addition to setting up giant cell reactions. Significantly, this fraction gave color tests characteristic of denatured proteins. Since prolonged high pressure homogenization was fairly effective in preventing lesion formation, it

is probable that the particulate material was rendered small enough to escape being caught in the capillaries. This precludes the possibility of a chemical inactivation of the causative factor(s). The material which comprised fraction A(F2) would be present in fraction B(F1) of the first fractionation. The latter fraction caused extensive lesions. The material present in fraction C(F2) would consist of fat, fatty acids, sterols, lipid degradation products, waxes, and other substances soluble in an acetone ether mixture. From the standpoint of lesion production this fraction was of low potency. Its removal from the phosphatides is warranted, if for no other reason than its lack of emulsifying properties.

Fraction B(F2) should consist mainly of phospholipids and represents most of those originally present, for in practice an overall yield of 90 per cent is obtained. This fraction proved to be the most efficient for our purposes. In Experiment 8 a blended preparation with particle size varying from 1 to 2 μ was injected into six rats without producing lesions, in Experiment 12 it was injected as part of a 30 per cent fat emulsion (Emulsion 35) into six rats of which five were found free of lesions and the remaining animal showed only one small lesion in one lung. That this fraction is a good emulsifying agent is indicated by the fact that a 30 per cent coconut oil emulsion can be stabilized with 3 per cent of the fraction. Preparations of fraction B(F2) which have been kept at -7° C for three months still retain their emulsifying properties. From Experiment 9 it can be seen that the injection of a crude mixture of fraction B(F2) in which the particles were 1 to 8 μ gave only a few one plus lesions. This suggests that within limits the particle size of these phospholipids is not of itself of great importance.

The twelve control rats for these assay experiments did not show the granulomatous lesions of the lung that had followed the injection of fractions other than B(F2).

The puppy experiments were of interest because they showed that fat could be given intravenously to this species without producing the extensive granulomatous lesions that had characterized all of our previous work. Also these studies were our first experiments with the administration of fat intravenously to growing animals. The fat emulsion used (Emulsion 35) contained 30 per cent coconut oil and was stabilized with a concentration of 3 per cent of fraction B(F2). The fat emulsion was well tolerated by the three puppies that received it depending largely on how rapidly it was given, particularly during the first few days of infusion. The growth and metabolic data of these puppies will form part of the substance of a subsequent report.

SUMMARY

A procedure to assay fat emulsions for intravenous use and the constituents of such emulsions has been developed using the albino rat.

Using this assay procedure confirmatory evidence was obtained that the soybean phosphatide material used as an emulsifying agent in our previous experiments was the principal cause of the granulomatous lesions observed following the intravenous administration of fat emulsions.

Chemical fractionation of the soybean phosphatide preparation was accomplished so as to yield a fraction with good emulsifying properties and little or no lesion-producing properties

A 30 per cent fat emulsion (Emulsion 35) was given in daily intravenous infusions to three puppies in varying amounts and for periods of time varying from thirty to eighty-four days without producing the granulomatous lesions found in previous experiments with adult dogs

VI FAT EMULSIONS FOR INTRAVENOUS NUTRITION THE TURBIDIMETRIC DETERMINATION OF INFUSED FAT IN BLOOD AFTER INTRAVENOUS ADMINISTRATION OF FAT EMULSIONS

ROBERT P GEYER, PH D, GEORGE V MANN, M D, AND FREDRICK J STARE, M D
BOSTON, MASS

ONE phase of the research on the intravenous use of fat emulsions has been the determination of the rate of disappearance of the infused fat from the blood¹. The usual methods for determining blood lipids are laborious and time consuming, and even the microadaptations of these methods require quantities of blood large enough to prohibit repeated use on small laboratory animals. Therefore the turbidimetric method described in this paper was developed. It has the advantage of requiring only 20 cmm of blood for a rapid accurate determination. Thus, numerous samples may be taken and the animals' ability to remove infused fat from the blood stream can be easily ascertained. The term "fat tolerance curve" is proposed for the graphic representation of the data obtained.

The present paper gives the method used, proof of its validity and the fat tolerance curves of the rat, dog, and rabbit when given 30 per cent fat emulsions.

EXPERIMENTAL

Principle of the Method—After the intravenous infusion of a fat emulsion the blood plasma becomes turbid. This turbidity is measured in a photoelectric colorimeter* and the amount of infused fat is calculated from a standard curve of K value. Within limits the turbidity bears a straight line relationship with the instrument readings and fat concentration. By taking successive samples of blood after an infusion of fat, a fat tolerance curve can easily be obtained by plotting the turbidity readings against time.

Materials Used—

1 Thirty per cent coconut oil emulsion. The composition, preparation, sterilization, and determination of particle size of this emulsion (Emulsion 35) have been described previously.²

2 Five per cent dextrose solution

3 Concentrated ammonium hydroxide

4 Superoxol. Thirty per cent solution of hydrogen peroxide

Preliminary Studies—Originally the method used was to read the turbidity of a diluted sample of plasma in the photoelectric colorimeter using filter

* Klett Summer on photoelectric colorimeter was used in these studies.

No 66 This filter was chosen because the presence of small amounts of hemoglobin had little effect upon the readings. Investigation demonstrated that the turbidity read, however, was the summation of that of the fat and of extraneous turbidity caused by a reaction between the emulsion and plasma. This interfering turbidity could be removed by the addition of a small amount of ammonium hydroxide without influencing the fat emulsion. It was also found that the emulsion component responsible for the false turbidity reading lay in the phosphatide preparation used. Microscopic dark-field examination of a mixture of phosphatide and plasma revealed many nonspherical, highly refractile bodies which could be made to dissolve by touching the edge of the liquid under the cover glass with ammonium hydroxide. This phenomenon was not observed with either the phosphatide or the plasma alone. The following experiment was carried out to study quantitatively the reaction between the plasma and the phosphatide and also to determine whether the ammonium hydroxide influenced the fat emulsion. A 30 per cent fat emulsion was diluted with water and 4 ml samples were pipetted into standard Klett tubes. Various amounts of clear dog plasma were added and after thorough mixing the tubes were filled to the 5 ml mark with water. The turbidities were read and then to each tube was added 0.05 ml of concentrated ammonium hydroxide. After mixing, the turbidities were again read. The results of this experiment are shown in Fig 1.

Fig 2—Standard curve showing instrument readings (R) plotted against fat concentration in diluted emulsion. (Above R or 220 the curve is no longer linear.)

In an effort to make the method more sensitive without necessitating the use of larger blood samples, two changes were made. First the standard Klett tubes were replaced with microtubes, and second, filter No. 42 was used in place of No. 66. To remove any hemoglobin which might be present various oxidizing reagents were tried and it was found that hydrogen peroxide was most satisfactory. The following experiment illustrates the effect of the peroxide treatment on the hemoglobin and the fat emulsion. Four milliliter aliquots of a diluted emulsion were placed in standard Klett tubes to which were added various quantities of a hemoglobin solution containing 29 mg of hemoglobin per milliliter. The tubes were brought to the 5 ml mark with water and the turbidities were read using filter No. 42. To each tube was added 0.05 ml of Superoxol and the tubes were heated in a water bath at 60° C for five minutes. After cooling to room temperature the turbidities again were read in the colorimeter. The results are shown in Fig. 1. It is necessary that the tubes be cooled to room temperature before turbidity readings are taken, otherwise the results will be significantly low.

Adopted Procedure—By means of a hemoglobin pipette 20 cmm of blood are collected and discharged into 2 ml of 5 per cent dextrose solution contained in a 13 by 100 mm Pyrex test tube and the pipette is rinsed in the usual manner. If any clotting occurs the sample should be discarded. The contents of the tube are well mixed by rotation and the tube is centrifuged at 1300 revolutions per minute for ten minutes. The supernatant is decanted into a Klett microtube, care being taken to avoid carry over of the sedimented cells and 0.05 ml of concentrated ammonium hydroxide is added, after mixing 0.05 ml of Superoxol is added. The tubes are heated in a water bath at 60 to 65° C for four minutes and then cooled to room temperature. Any moisture which has condensed on the sides of the tube is mixed in, and any bubbles of gas attached to the sides of the tube are removed by gentle tapping. The turbidity is read in the colorimeter using filter No. 42.

A standard curve is obtained by making various dilutions of the emulsion using 5 per cent dextrose solution as the diluent. Two milliliter quantities of each dilution are placed in the microtubes and the tubes are carried through the procedure outlined in the preceding paragraph. The turbidities obtained are plotted against the concentration of fat. Where greater accuracy is required the standard curve can be made with 15 ml samples, and in the procedure for the unknown, instead of simply decanting as much of the supernatant as possible a 15 ml aliquot can be taken. This would make the dilution effect of the reagents a constant throughout. In routine practice however it is sufficient to use the method outlined. A typical standard curve is given in Fig. 2.

Comparison With Microoxidation Method—A rabbit weighing 4310 grams was given an injection by ear vein of 12 ml of the emulsion in the course of two minutes. At intervals 2 ml samples of arterial blood were taken and immediately heparinized. After centrifuging at 1300 revolutions per minute for fifteen minutes, 20 cmm of the plasma were added to 2 ml of 2 per cent dextrose solution contained in Klett microtubes. The tubes were carried

Fig 3

Fig 4—Fat tolerance curves of various species following intravenous administration of $1\frac{1}{2}$ Gm of fat per kilo of body weight

Fig 4

through the regular procedure and the turbidities were read in the colorimeter. Concurrently, suitable aliquots of each of the plasma samples were taken and carried through Boyd's modification³ of Bloo's microoxidation method for total fatty acids plus cholesterol. The results of this experiment are given in Fig 3.

Fat Tolerance Curves—The tolerance curves of three species of animals to a 30 per cent coconut oil emulsion (Emulsion 35) and of one species (the rabbit) to a 30 per cent mineral oil emulsion were determined. Several rabbits, dogs, and rats each were given 5 ml of emulsion per kilogram of body weight at the rate of 2 ml per minute. The rabbits were injected by ear vein, the dogs by leg vein, and the rats by tail vein. Turbidity curves were obtained on venous blood using the procedure given previously. The results of these experiments are shown in Fig 4 where each curve represents one animal of each species.

DISCUSSION

The turbidimetric determination of infused fat in the blood following intravenous administration of a fat emulsion can be quickly accomplished with only 20 cmm of blood. It is essential that the emulsion be stable in the blood and to subsequent treatment with the reagents used. It is equally important that hemoglobin and extraneous turbidity be removed. As shown in Fig 1 and Table I these conditions have been adequately met. That the values agree well with a conventional microoxidation method is shown in Fig 2. It is to be ex-

pected that the curve obtained by turbidimetric means would be lower than that found by the microoxidation method, especially as the latter has been employed here, since total fatty acids plus total cholesterol have been determined. The turbidimetric method determines principally the infused neutral fat, because the normal turbidity of the plasma lipids is extremely low. That a change in instrument and conditions might allow the determination of the normal colloidal lipids in plasma is indicated by the report of Moreton.⁴ In several instances chylomicriographs⁵ have been determined simultaneously with the turbidity curves after a fat emulsion injection. Agreement between the resulting curves was good.

The reaction between the phosphatide and plasma which gives rise to the extraneous turbidity observed may be similar to that reported by Chargaff and Ziff⁶ to occur between cephalin and basic proteins. A large percentage of the phosphatide is made up of cephalins, and *in vitro* tests have shown that when the pH of a mixture of plasma and phosphatide is lowered, a voluminous precipitate is formed. Neither the plasma nor phosphatide alone will form such a product. The resulting precipitate when washed with water, acetone, and petroleum ether was insoluble in water but readily dissolved in a weak ammonium hydroxide solution. Reprecipitation results if the solution is reacidified. What plasma protein is involved is unknown at present. In agreement with the findings of Chargaff and associates⁷ is the fact that the phosphatide reacts with oxyhemoglobin and on acidification yields a reddish brown precipitate. The latter is soluble in dilute ammonium hydroxide and this may explain why, as shown in Fig. 1, the turbidity decreased slightly when NH_4OH was added even though no plasma was present.

*Rabbit plasma.

†Instrument readings made with filter No. 4.

The removal of the hemoglobin by the hydrogen peroxide is complete when the amount of hemoglobin does not exceed that normally present. Where hemolysis is excessive recourse to filter No. 66 can always be taken. It is usually possible to avoid mechanical lysis of the cells. The fact that the peroxide treatment has no effect upon the emulsion is further indication of the latter's stability.

The term fat tolerance curve designates the rate at which infused fat leaves the blood stream and it is possible that like the glucose tolerance curve it may

become of diagnostic importance. Studies are now in progress on this phase of the problem. Such curves are a convenient guide in the use of fat emulsions for intravenous nutrition. It is of interest that the rabbit, which normally ingests little fat, cleared the infused fat at a slower rate than either the rat or dog whose diet is usually higher in fat (see Fig. 4). The slow removal of the mineral oil emulsion is also of interest because the oil concerned is non-hydrolyzable. Further work with this oil may reveal the reason for this slow removal. Unlike the blood lipid curve which results after oral fat intake, the curve obtained after a fat emulsion infusion is not subject to the influence of new lipid continually entering the blood. Perhaps by knowing the animals' ability to use infused fat, the curve obtained by oral fat ingestion could be corrected to give a clearer picture of the rate of absorption from the intestine. This would assume that normal blood fat and infused fat are handled by the body in the same manner.

SUMMARY

A simple turbidimetric method is described for determining the level of infused fat in the blood after intravenous administration of a fat emulsion.

The effects of hemoglobin and extraneous turbidity are discussed and the method of their removal is given.

The method is compared with the microoxidation method for blood lipids.

Fat tolerance curves are given for the dog, the rat, and the rabbit. The difference between the behavior of mineral oil and coconut oil in the rabbit is shown.

STUDIES ON THE CONGLUTINATION TEST IN ERYTHROBLASTOSIS FETALIS

ALEXANDER S. WIENER, M.D. and ELLIOT B. GORDON
BROOKLYN, N. Y.

THE original method¹ (blocking test) of demonstrating univalent antibodies (blocking antibodies or glutinins) was indirect and therefore relatively insensitive. The conglutination test² for univalent antibodies, on the other hand, is a direct and more sensitive test and therefore has proved more satisfactory. While in saline media univalent Rh antibodies merely "coat" Rh positive cells by combining with the specific antigen without producing any visible reaction, in plasma or serum media clumping of the coated red blood cells occurs. As has been demonstrated in previous papers,³ this clumping is not due to agglutination but to conglutination. The plasma contains a third component conglutinin, a colloidal complex of plasma proteins, which is adsorbed by the specifically sensitized red blood cells, causing them to stick together. On the other hand, agglutination in saline media is as distinct as or more distinct than in plasma media because the agglutinins (bivalent antibodies) bind the cells together directly without the intervention of any third component.

On the basis of these considerations, it was postulated that univalent antibodies are composed of smaller molecules than bivalent antibodies and therefore traverse the placenta more readily than the latter.^{4,5} Ample direct and indirect evidence^{6,7} confirming this prediction has now been obtained showing that univalent Rh antibodies as well as univalent alpha and beta and other antibodies pass through the placenta early in the third trimester of pregnancy and accumulate in the fetal body until the titers in the fetal and maternal plasmas become equal. Where the fetus is Rh positive or belongs to an incompatible A B group, the antibodies are first taken up by the red blood cells or tissues and only after these are coated do free antibodies accumulate in the plasma. In these cases if the baby is born alive, the red blood cells at birth are coated with univalent antibodies and it was found that this could be demonstrated simply by the conglutination technique.⁸ One of the purposes of this paper is to describe the results obtained with this test in a series of cases of Rh sensitization, and to compare the test with the antiglobulin method of Coombs and coworkers⁹ and Hill and Harberman.¹⁰

At this point it may be of interest to mention other predictions made on the basis of the conglutination theory,³ which have been confirmed subsequently. A characteristic of erythroblastosis fetalis is that many babies appear normal or only mildly affected at birth but within a few hours jaundice becomes evident and rapidly increases in intensity, and the disease often terminates with the death of the infant within a day or two. Such infants usu-

From the Transfusion Division of the Jewish Hospital of Brooklyn and the Serological Laboratory of the Office of the Chief Medical Examiner of New York City.

Received for publication Oct. 30, 1947.

all present the postmortem findings of kernicterus and liver necrosis. This sequence of events occurs whether delivery takes place at term or whether the pregnancy is terminated prematurely by cesarean section or by induced labor. This indicates that the birth itself must precipitate the progress of the disease. It was reasoned that while the child was in utero the fetal cells did not clump because fetal plasma must be deficient or lacking in conglutinin. However, the profound physiologic changes occurring at birth could result in abrupt increase in the conglutinin content of the plasma causing the coated red blood cells to clump (by conglutination), thus blocking the circulation to vital organs. Direct measurements of the conglutinin content of fetal plasma confirmed this prediction that the amount present is small and that the conglutinin content increases after birth, though not to the level characteristic for adult plasma. It is interesting that complement has a similar development, considering that complement has an analogous role in serologic lysis to that of conglutinin in the conglutination reaction.

Still another surmise made in connection with the conglutination theory is that conglutinin is probably identical with or related to the γ protein of Pedersen.¹¹ According to Pedersen γ protein is a reversibly dissociable complex of albumin and globulin, present only in concentrated plasma or serum because slight dilution with aqueous solutions causes it to dissociate into its constituent molecules of albumin and globulin. In parallel with the behavior of γ protein, we found that relatively slight dilution of plasma with isotonic aqueous solutions causes it to lose its conglutinating activity. Conversely, we reasoned that it should be possible to produce conglutinin by mixing solutions of albumin and globulin. We did find that when a 4.6 per cent solution of human globulin and a 12.5 per cent solution of human albumin, both of which had little or no conglutinating activity, were mixed so as to produce a solution with a total protein content and albumin:globulin ratio equivalent to that of normal blood serum, the resulting mixtures proved to have a high conglutinating activity, even exceeding that of normal plasma. Here again the analogy between conglutinin and complement holds, since this may be compared with the experiments with so called midpiece and endpiece.

Obviously, the sensitivity of the conglutination test will depend not only on the titer of the univalent antibody but also on the quality of the conglutinin. While the original description of the test called for the use of inactivated serum, we soon adopted the use of oxalated plasma⁴ because the latter has a higher conglutinating activity and is relatively free of rouleau forming properties. Moreover, it was found that while pure albumin itself was inferior to oxalated plasma, nevertheless the addition of small amounts of albumin to plasma enhanced the latter's conglutinating activity,⁵ presumably because the added albumin combined with the natural conglutinin in the plasma to form a more active complex. Based on this observation, the albumin plasma conglutination test was devised,³ which must not be confused with the albumin test of Drimond and Denton¹² since the latter calls for a pure 25 per cent solution of human albumin or a pure 30 per cent solution of bovine albumin without any plasma.

MATERIALS AND METHOD

The material which formed the basis for the present study consisted mainly of infants born to Rh negative women who had been studied during the prenatal period for the presence of Rh sensitization. Our series is a selected one in that many of the pregnant women were referred to us either because they had previously had erythroblastotic infants or because they had been found to be Rh negative in the course of routine Rh antibody examinations. In a few cases we were not called to see the affected infants until after birth, either because antenatal tests had not been done or because the mother had been incorrectly typed during pregnancy as Rh positive.

At the first interview, the expectant mother's blood was completely classified for blood group, MN type, and Rh Hr type, and the same tests were made on the husband to determine, if possible, whether he was homozygous or heterozygous for the Rh factor. Moreover, antibody tests were done periodically on the prospective mother's serum, and, based on the Rh Hr tests and antibody titrations, predictions were ventured as to the type and severity of

the disease in the infant. The affected infants were mostly treated by exchange transfusion, as will be reported elsewhere.¹³ As also will be shown in a separate report the manifestations closely corresponded to the predictions and in a number of cases the infants were delivered prematurely by cesarean section or by induced labor in order to prevent stillbirths and to treat the infants by exchange transfusion.¹⁴ Where possible samples of the cord blood were obtained in order to test the red blood cells for coating with univalent antibodies and to examine the infant's serum for free Rh antibodies and to determine the icterus index. In the few cases where the cord serum could not be obtained because the infant was seen after birth, these determinations were carried out on the first sample obtained at the exchange transfusion.

The Rh antibody titrations on the maternal and infant sera were carried out by the agglutination and albumin plasma conglutination methods, as described in previous papers.^{3, 4} In some cases the sera were also titrated by the plasma conglutination method and blocking method but the o titers are not included in Table I in order to avoid complicating the presentation. All titrations were done at least two times against test cells of types Rh₁ and Rh and the titer values obtained were averaged. In testing for coating of the fetal cells 2 drops of a 2 per cent saline suspension of the red blood cells were centrifuged and the supernatant fluid removed completely and replaced by a drop of compatible plasma or albumin plasma mixture.¹⁵ The red cells were resuspended and after incubating for forty five minutes at body temperature the preparation was examined for the presence of clumping. The saline suspension itself of the infant's cells invariably showed no trace of clumping. Control tests were always carried out on normal red cell suspensions to show that the plasma albumin mixture was incapable of clumping such cells. For the antiglobulin test an anti human precipitin serum was absorbed with washed packed, and pooled A and B cells to remove all heteroagglutinins. The actual tests were carried out by adding this reagent (diluted 1:2 or higher depending on its titer) to 1 drop of thrice washed saline suspension of infant's red blood cells, readings being taken after forty five minutes of incubation at body temperature.

The icterus index determinations were made by the acetone precipitation method.

Titration of sera containing univalent antibodies by the antiglobulin technique were carried out in the following manner. To a series of tubes containing 1 drop each of a series of progressively doubled dilutions of the serum 1 drop of a 2 per cent saline suspension of Rh positive cells was added and the mixtures allowed to react in the water bath for one hour. The red cells were then washed three times with saline solution. After the third washing the sediments were resuspended in 1 drop of saline solution, and 1 drop of the absorbed anti human precipitin serum was added. The mixtures were incubated for another hour after which the reactions were read.

RESULTS

Nine different sera from sensitized Rh negative women were titrated by the blocking, plasma conglutination, albumin plasma conglutination, and anti globulin techniques in order to compare the relative sensitivities of these methods of detecting univalent Rh antibodies (see Table I). Two of the sera tested (Sera 8 and 9) contained agglutinins as well as univalent antibodies. In accordance with our previous report,³ the blocking test gave the least sensitive results, and the plasma conglutination test was on the average about ten to fifteen times as sensitive as the blocking test, while the albumin plasma conglutination test was on the average about four times as sensitive as the plasma conglutination test. As shown in Table I, the antiglobulin technique gave results roughly corresponding to those obtained by the plasma conglutination test, being less sensitive than the albumin plasma method.* It is felt that the

*The experiments were repeated several times using at least three different precipitin sera for the antiglobulin test always with similar results.

albumin-plasma method is to be preferred to the antiglobulin technique, since the former is much simpler to perform and gives more sensitive results

In Table II are summarized a series of cases in which Rh-negative mothers and their infants were studied serologically for evidence of Rh sensitization. For clarity in discussing the findings, the cases have been divided into four groups as follows

1 Eleven cases in which the maternal serum contained univalent antibodies without detectable agglutinins. They are arranged according to the titer of the antibodies immediately prior to or following delivery

2 Eight cases in which the maternal serum contained Rh agglutinins with or without Rh univalent antibodies

3 Three cases of sensitized Rh-negative women who gave birth to normal Rh-negative infants

4 Four control cases of nonsensitized Rh-negative women with normal Rh-positive infants

We have omitted from this table those cases in which the mother was sensitized to the A and B factors as well as to the Rh factor, these complicated cases of double sensitization will be discussed in a later paper. Two cases (Cases 16 and 25) have been included in the table in which the baby's blood group was incompatible with the mother's, but in these cases the maternal anti-A and anti-B titers (by the conglutination as well as by the agglutination technique) were lower than average, showing that the mothers were not sensitized to the A or B factors

It would be expected that in all cases where the maternal serum contains a high titer of univalent antibody the infant would be born with its red cells completely coated with blocking antibodies. Where the maternal antibody titer is low, on the other hand, the red cells of the erythroblastotic infant would be expected to be only partly coated. As shown in Table II, this prediction was actually fulfilled in our series of cases. Thus, the Rh-positive red cells of the erythroblastotic infants of the most strongly sensitized mothers (Cases 1, 2, 3, 4, 5, 6, 7, 10, 12) failed to clump in anti-Rh₀ agglutinating serum, due to complete blocking of the cells. Moreover, with two exceptions (Cases 1 and 3) these

cells clumped (conglutinated) when suspended in compatible plasma or in albumin-plasma mixture

The failure of the red cells of the infants of Cases 1 and 3 to conglutinate is contrary to expectation and calls for an explanation. The following plausible hypothesis suggests itself. As has already been demonstrated,^{2, 5} fetal plasma is deficient in conglutinin in comparison with adult plasma. Also, there is reason to believe that fetal conglutinin differs in quality as well as quantity from adult conglutinin. Thus one may postulate that fetal plasma contains conglutinoid, a substance analogous to so-called complementoid.¹⁶ In cases in which the fetal red cells are strongly sensitized by univalent antibodies, they will absorb conglutinoid from the fetal plasma, but conglutinoid, unlike conglutinin, fails to clump the cells, just as complementoid is adsorbed by sensitized cells but fails to lyse them. When an infant's sensitized red cells, which have adsorbed conglutinoid, are suspended in plasma they will fail to clump or clump only feebly because the conglutinoid will block the adsorption of conglutinin. Supporting this concept is the observation that such red cells are clumped strongly by antiglobulin serum even though the antiglobulin technique is ordinarily less sensitive than the albumin-plasma conglutination technique for demonstrating univalent antibodies, as has already been pointed out (Table I).

In accordance with expectations, when the maternal univalent antibody titer is very high, not only are the infant's red cells completely blocked but also free circulating antibodies can be demonstrated in the fetal plasma. Where the maternal antibody titer is low, the infant's red cells are not blocked, but partial coating of the red cells can be demonstrated by the more sensitive conglutination technique (see Cases 8 and 9, Table II).

Where the maternal serum contains bivalent Rh antibodies, one would expect that the infant's red cells at birth would not be coated with univalent Rh antibodies. As is shown in Table II, this was true in only half the cases in our series. To account for coating of the infants' cells in Cases 12, 13, 16 and 18, one must postulate that the maternal serum contained univalent as well as bivalent Rh antibodies but that the former were weaker so that they were masked by the agglutinins. In support of this idea, it may be pointed out that in two cases (Cases 13 and 16) the infants' sera contained free univalent Rh antibodies.

Of special interest are Cases 20, 21, and 22 where sensitized Rh-negative women gave birth to Rh-negative children. As expected, none of these infants were erythroblastotic. In two of the cases where the maternal serum contained pure univalent antibodies, the infants' sera contained univalent antibodies of equal titer. In the third case, where the maternal serum contained moderately strong (24 units) Rh agglutinins, the infant's serum contained no Rh agglutinins but univalent Rh antibodies of $2\frac{1}{2}$ units. In the latter case, presumably, the maternal serum also contained Rh univalent antibodies of $2\frac{1}{2}$ units titer, but these were masked by the Rh agglutinins. Thus, the placenta acts as a semipermeable membrane which permits the free passage of univalent antibodies but holds back bivalent antibodies.

In the four control cases* in which the maternal serum contained no Rh antibodies, the infants, though Rh positive were not erythroblastic and the red cells showed no evidence of coating.

Of considerable importance is the correlation between Rh antibody titer and the severity of the disease in the fetus and infant. Where the maternal serum contains univalent antibodies which readily pass the placental barrier a good correlation is to be expected. On the other hand if the maternal serum contains only bivalent antibodies, the titer may be less important than other factors such as an accidental defect in the placental barrier or increased intrauterine pressure causing the antibodies to enter the fetal circulation.⁶ These expectations have been fulfilled in our series of cases. When the maternal serum contains potent blocking antibodies the Rh positive fetus is invariably delivered as a macerated stillbirth such cases were not included in Table II because the fetal blood in these cases was not suitable for examination. It is significant that of the cases listed in Table II the four babies that died in spite of treatment came from the mothers with the highest titers of univalent antibodies. Similar observations showing the correlation between quality and quantity of antibody and prognosis have been made by Sicks and associates¹ and by Torregrossi¹³ in conformity with Wiener's theory,⁸ and more recently by Davidson.¹²

SUMMARY

Of the various methods of demonstrating univalent Rh antibodies, the blocking test is the least sensitive the plasma agglutination test is about ten times as sensitive as the blocking test, and the albumin plasma agglutination test is about four times as sensitive as the plasma agglutination method. The antiglobulin technique is about equal in sensitivity to the plasma agglutination technique.

When the maternal serum contains univalent Rh antibodies, these antibodies pass through the placenta and coat the infant's Rh positive red cells as can be demonstrated by the blocking agglutination, and antiglobulin techniques. The higher the titer of the univalent antibody in the maternal serum, the more completely are the fetal red cells coated and the more likely is the fetal plasma to contain free Rh antibody.

When the maternal serum contains bivalent antibodies the fetal red cells will not be coated unless the maternal serum also contains univalent Rh antibodies.

When an Rh negative woman with univalent Rh antibodies has an Rh negative baby the baby will not be erythroblastic but its plasma will contain univalent Rh antibodies equal in titer to that of the maternal plasma at the time of birth.

Rh agglutinins usually are not demonstrable in the plasma of an Rh negative infant even when the maternal serum contains a high titer of these antibodies.

*Many more such cases have been studied but four are sufficient for purposes of illustration.

The placenta acts as a semipermeable membrane which permits the passage of univalent antibodies but holds back bivalent antibodies

Infants of nonsensitized Rh-negative women are not erythroblastotic provided other sensitizations are also excluded, for example A-B sensitization

Where the maternal serum contains univalent Rh antibodies, the severity of the manifestations in the erythroblastotic infant is roughly proportional to the antibody titer

Evidence is presented suggesting the presence of a substance in fetal plasma, conglutnoid, which is adsorbed by cells sensitized by univalent antibodies but fails to clump them. Conglutnoid seems to be capable of blocking the action of conglutinin in much the same way that so-called complementoid blocks the action of complement

A STUDY OF CHOLINESTERASE ACTIVITY OF THE BLOOD OF PATIENTS WITH PERNICIOUS ANEMIA

LEO M MEYER, M D , ARTHUR SAWITSKY, M D,* NORTON D RITZ, M D , AND
HOWARD M FITCH, PH D
BROOKLYN, N Y

IN 1940, Sabine¹ reported red cell esterase rises with concomitant plasma and whole blood esterase reduction in two phlebotomized dogs. In a study¹ of fifteen patients with various types of anemias she reported low plasma esterase activity in debilitated and comatose states. The red cell esterase activity in these patients did not parallel that of the plasma. In general, the red cell and plasma activities were lower in those patients with hematocrits less than 30 per cent and there was normal activity where the hematocrit was above this value. Three patients with pernicious anemia in relapse receiving liver therapy were studied during their recovery. Initially, the whole blood, red cell, and plasma esterase activities were low. During treatment the cell esterase returned to normal levels in four to nine days. This was followed by a further increase in activity and a decline to normal levels in about six weeks. The plasma esterase responded much more slowly, rising to normal in about six weeks.

Previously, Antopol² and associates reported a general lowering of serum esterase in patients with secondary anemias and acute hemolytic anemia. Hall and Lucas³ found no correlation between the serum esterase activity and the hemoglobin concentration, red cell and white cell counts. Ginsberg, Kohn, and Necheles⁴ found that washed pus cells had no esterase activity. Milhorat⁵ reported lowered serum esterase in patients with leucemia. He noted no correlation between the serum esterase and the hemoglobin or between the serum esterase and the red cell count of the peripheral blood. There is general agreement that the plasma or serum cholinesterase activity is decreased in debilitated states^{1, 5, 7} and in liver and biliary tract diseases^{2, 6, 7}. Low normal values are found in association with acute infections³. Hall and Lucas³ could not demonstrate any relationship between the serum esterase activity and age, sex, diet, body activity, heart rate, or blood pressure in normal and pathologic sera. The role of cholinesterase in myasthenia gravis and the neuromyopathies is not clear. In these diseases the red blood cell esterase is reported to be normal while the plasma esterase is generally reduced.^{7, 8}

Since 1944 a series of articles has been published by Davis and co-workers¹⁰⁻¹⁴ concerning the experimental production of a hyperchromic anemia in dogs which responds to antipernicious anemia therapy. Interestingly enough one report¹³ contains a description of nervous system changes similar to the neuropathologic changes noted in human pernicious anemia. Concomitant

From the Medical Service of Kings County Hospital and the Department of Therapeutics New York University College of Medicine New York City

A preliminary report of these data was presented at the Hematology Study Section of the National Institute of Health Bethesda Md Feb 15, 1947

Received for publication Aug 25 1947

Lederle Fellow in hematology

with the production of the anemias, the cholinesterase activity of the dog sera fell to a low value. With the institution of antipermeious anemia therapy, the red cell count, hemoglobin and esterase activity of the serum returned to normal levels. In 1946, Davis^{11, 12, 14} reported that folic acid could be used in place of liver extract. He also stated that folic acid administered to normal human subjects increased the serum esterase activity significantly within five hours. During the same year, he observed an increase in an acetylcholine-like substance in the blood of patients with pernicious anemia which returned to normal levels after antipermeious anemia therapy.¹² At this time he noted that the serum esterase activity paralleled the rising red cell count.

This report is concerned with the study of the cholinesterase activity of whole blood, red cells, and plasma in patients with pernicious anemia treated with folic acid and with combined folic acid and liver extract therapy.

METHODS

Seven patients with pernicious anemia in relapse were studied. The diagnosis was made on the basis of the peripheral blood picture, a megaloblastic bone marrow, the absence of free hydrochloric acid in the stomach, the absence of gastrointestinal disease after fluoroscopic and x-ray study, and guaiac negative stools. A reticulocytosis following adequate antipermeious anemia therapy was always noted.

Baso lines for reticulocytes, hemoglobin, red cells, and cholinesterase activity were established before treatment was given. Cholinesterase activity was determined in the oxalated venous blood before and during the course of therapy.

Cholinesterase activity was measured by the method described in a previous report.¹⁴

CASE REPORTS

CASE 1—M. F., a 70-year-old white woman, known to have pernicious anemia of several years' duration, sought treatment because of weakness, dyspnea, and sore tongue. Because of liver sensitivity she had had no therapy for the previous four months. Prior to that, treatment had been intermittent and irregular. Physical examination revealed a sore red tongue. The liver and spleen were not palpable. The gait was normal and the Romberg was negative. The knee jerk reflex was hyperactive and the Babinski sign was bilaterally positive. Position and vibratory sense were normal.

Laboratory Data—The stools were negative for occult blood. Gastric analysis revealed achlorhydria after histamine. The cephalin cholesterol flocculation was 1 plus and the icterus index was 10. The blood urea nitrogen was 15 mg and the blood sugar was 90 mg per 100 ml of blood. The urine was normal. The bone marrow was not studied. Peripheral blood counts are shown in Table I.

The patient was given 20 mg of folic acid by mouth daily in the form of an elixir. Seventy-two hours later improvement of appetite and general status was noted. In one week the tongue symptoms were relieved. After three weeks, neurological examination disclosed no abnormalities.

Before treatment the cholinesterase activity of the blood was low (about one-half the normal range). On the fourth day of therapy there was a simultaneous rise in the reticulocytes and an increase of the mean cell volume and mean cell esterase. Reticulocytosis was maintained for sixteen days. The corpuscular esterase activity reached a peak of 120 ($\times 10^{-10}$) units (normal, 619 to 869 [$\times 10^{-10}$] units) on the twentieth day of treatment and returned to normal levels about the thirty-sixth day. The mean corpuscular volume tended to parallel the reticulocyte curve, reaching a peak on the eighth day and returning to normal levels on the thirty-sixth day. The plasma esterase values remained constant throughout.

Fig 1

The erythrocyte count was not significantly increased until the eleventh day. Mean corpuscular hemoglobin gradually decreased, reaching the normal range about the thirty-sixth day.

CASE 2—M P, a 73-year-old Negro woman, was admitted to Kings County Hospital complaining of weakness and weight loss of three months' duration. There was no history of bleeding. Physical examination revealed an extremely pale, malnourished Negro woman. She was disoriented, incoherent and belligerent. The only other positive finding was bilaterally hyperactive knee jerk reflexes.

Laboratory Data—The stools were negative for blood and gastric analysis revealed histamine refractory achlorhydria. A gastrointestinal series and a barium enema study disclosed no abnormalities. The total blood proteins were 5.8 Gm. per 100 milliliters. The other blood findings per 100 ml. were: calcium, 9.8 mg.; phosphorus, 3.5 mg.; urea nitrogen, 15 mg.; blood sugar, 86 milligrams. The alkaline phosphatase was 4.1 units and the icterus index, 1.9. The bone marrow showed 30 per cent megaloblasts. The peripheral blood picture is shown in Table I.

Treatment of the patient was begun and 1 unit of liver extract combined with 0.3 mg. of folic acid was given intramuscularly daily. For the first twenty-two hours sedation was required. A diarrhea was noted which persisted for the following ten days. After ninety-six hours the appetite was improved and general clinical improvement was noted. The reticulo-

FIG 2

cyte response and the cholinesterase activity are shown in Fig 2. The patient made an uneventful recovery and on discharge was instructed to take 30 units of liver extract twice weekly.

The initial esterase values were obtained on the second day of therapy and were low (about one half the average normal value). On the fifth day significant increases in red cell esterase and in the number of reticulocytes were noted. The erythrocyte count rose and the mean corpuscular volume and hemoglobin started to fall. The mean cell esterase activity continued to rise, reaching a peak on the eleventh day. The reticulocyte curve returned to normal about the eighteenth day. The corpuscular esterase fell more slowly, it was abnormally high after 36 days, but returned to normal by the seventieth day. The plasma esterase remained constant for twenty five days, then rose slowly, paralleling the erythrocyte increase.

Fig 3

CASE 3*—J J, a 70 year old white woman, was admitted to the Kings County Hospital complaining of progressive dizziness and tinnitus of four months duration. One week before admission weakness, blood tinged diarrhea, dysuria and polyuria were noted. A history of inadequate diet and the daily consumption of a pint of liquor for the past thirty years was obtained. On physical examination the only positive findings were a blowing apical systolic murmur, moderate right costovertebral angle tenderness, and external hemorrhoids.

Laboratory Data—A routine blood count revealed macrocytic hyperchromic anemia and 2 per cent megaloblasts in the peripheral blood. Bone marrow aspiration was confirmatory and a megaloblastosis of 32.5 per cent was noted. Gastric analysis was done and a histamine refractory achlorhydria was found. The chest x-ray and gastrointestinal series disclosed no abnormalities. Urine examination showed many white blood cells with clumping. The blood chemistry was normal.

From the Medical Service of Dr W. Doel and Dr R. Janet Watson, Kings County Hospital.

The patient was disorderly on admission and on the next day was disoriented and psychotic. She was given 0.5 mg of folic acid intramuscularly daily for twelve days. At this time 2 mg of beta pyracin were added to the daily dose. There was no clinical response, but a reticulocytosis of 52 per cent was observed. After ten days the daily administration of 10 mg of folic acid intramuscularly was started and a clinical and hematologic response followed. Nineteen days later, because of continued disordered sensorium, therapy was changed to the daily administration of 10 units of liver extract by the intramuscular route. After eighteen days of liver therapy the sensorium cleared and the patient made an eventual recovery.

The initial esterase values were low, averaging 5 units of red cell esterase, 6 ($\times 10^{-10}$) units of corpuscular esterase, and 18 units of plasma esterase. Following inadequate therapy with folic acid and beta pyracin, red cell and corpuscular esterase activities rose to a peak of about 9 units (in normal range) on the twelfth day and then fell rapidly to 6 units on the twenty-third day. A reticulocyte peak of 52 per cent was noted on the ninth day. The reticulocytes dropped to 18 per cent on the eleventh day and remained at about 1 per cent until seven days after folic acid in 10 mg doses was given, when another peak of 82 per cent was noted. The number of erythrocytes rose slightly during the first period and then fell off to pretreatment levels until effective folic acid therapy was given. Nine days later the red cell and corpuscular esterase rose sharply to a peak of 11.7 units and 13.0 ($\times 10^{-10}$) units, respectively. The plasma esterase remained relatively constant throughout.

Fig 4

CASE 4—Ve, a 75 year old white man who was seen by one of us (L M M), complained of weakness and loss of appetite during a period of one year. Six months previously he had been given a transfusion for "anemia" but no other therapy. Physical and neurological

examinations disclosed no abnormalities. A gastrointestinal series was normal and there was no blood in the stools. The blood findings were nonprotein nitrogen, 27 mg, and the fasting sugar, 90 mg per 100 ml, reticulus index 8. The patient was treated with 1 unit of liver extract daily for ten days and then single injections of liver extract in equivalent unit dosage were given at approximately weekly intervals.

Initially the red blood cell and mean corpuscular esterase activities were within normal limits. The plasma activity was only slightly decreased. Following liver therapy there was a small increase in the erythrocyte esterase activity. A maximal value was attained on the sixteenth day. This value was sustained for an equal period of time and then fell to a lower plateau within the normal range. The plasma esterase rose to normal on the nineteenth day.

Fig 5

day On the fourth day after therapy, a reticulocytosis was noted which reached a peak of 17.2 per cent on the seventh day The erythrocyte count rose steadily as is shown in Table II

CASE 5—G M, an 85 year old white man, was admitted to the Psychiatric Pavilion of Kings County Hospital because he was paranoid, abusive, hyperemotional, and unpredictable in his actions He was transferred to the Medical Service when a severe anemia was found Physical examination disclosed a well nourished man with a lemon yellow tint to the skin, icteric sclerae, and pale conjunctivae Neuropsychiatric examination elicited gross memory defect, lack of insight, and disorientation as to time and place

Laboratory Data—The urine analysis disclosed no abnormalities Histamine refractory achlorhydria was found The stools were free of blood The cephalin flocculation was negative and blood cholesterol was 153 mg per 100 milliliters A bone marrow aspiration revealed sheets of megaloblasts The peripheral blood findings are shown in Table I

The patient was difficult to manage and required restraint He was treated with 1 unit of liver extract intramuscularly daily, and a mild clinical but no hematologic response was noted Ten days later he was given 10 units of liver extract After six days he received fifteen units of liver daily intramuscularly There was clinical improvement, but a submaximal reticulocytosis was obtained The patient's mental status remained impaired and on the fortieth day of observation the patient was transferred to the psychiatric ward

The initial mean corpuscular esterase and red cell esterase activities were in the normal and low normal range, but the plasma activity was about one half of normal values Three days after the beginning of liver extract therapy the reticulocyte count rose, reaching a plateau of 4 to 6 per cent which was sustained for twenty two days The red cell esterase increased rapidly to 13.5 ($\times 10^{-10}$) units on the third day and then fell abruptly to the initial levels on the eighth day There was a secondary rise to 14 ($\times 10^{-10}$) units two days later, with a peak of 16.5 ($\times 10^{-10}$) units on the sixteenth day The red cell esterase values then slowly fell toward lower but normal levels The plasma activity was constant and low throughout the period of observation The mean cell volume was above normal for thirty days and then returned to normal The red cell count remained stationary at about 1,000,000 per c mm for sixteen days and then rose slowly toward normal This erythrocyte response was observed six days after the second red cell esterase rise

CASE 6—A P, a 50 year old white woman known to have pernicious anemia, was admitted to Kings County Hospital for weakness and pallor of six months' duration She had been treated fifteen months previously for pernicious anemia in relapse and had responded well to 0.5 units of liver and 10 mg of folic acid intramuscularly daily She stopped all medication eight months before the present admission Physical examination was negative

Laboratory Data—A gastrointestinal series was negative and the stools were negative for blood The cephalin flocculation was 1 plus, the alkaline phosphatase, 4 units, and the icterus index, 6 The blood total protein was 6.2 Gm per 100 milliliters The urinary urobilinogen was positive to a dilution of 1:10

The patient was treated with an experimental liver fraction without hematologic or clinical response After five days, oral treatment with 1 unit of liver and 5 mg of folic acid was started Within forty eight hours there was marked clinical improvement The patient went on to make an uneventful recovery The peripheral blood picture and the cholinesterase response are shown in Table II

The initial red cell esterase values were only slightly below the normal range and rose rapidly to normal following the injection of an experimental liver fraction There was no reticulocytosis and no erythrocyte rise was noted during this period Three days after adequate therapy with liver and folic acid was instituted a reticulocytosis ensued A peak of 24 per cent occurred on the seventh day On the thirteenth day, following combined oral liver and folic acid the mean cell cholinesterase activity rose above normal and reached a peak of 10.8 ($\times 10^{-10}$) units on the sixteenth day The red cell esterase gradually fell to normal values by the forty second day The erythrocyte count remained unchanged until eleven days

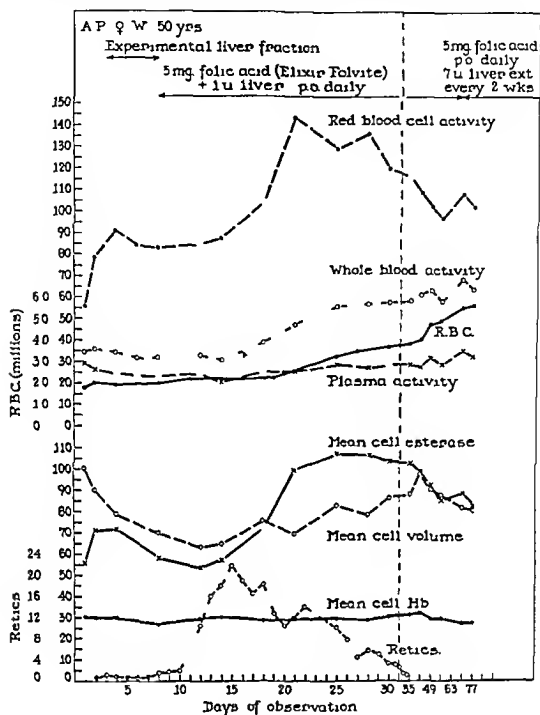

Fig 6

after combined therapy was given and then slowly rose to normal levels. There was an equivocal rise of the plasma activity seventeen days after the institution of combined therapy.

CASE 7—M O, a 56-year-old white man, was admitted to Metropolitan Hospital for pernicious anemia of one year's duration, anorexia, weakness, dyspnea on effort, and dysphagia of four months' duration. Diarrhea for three weeks prior to admission was also noted. The only significant findings on physical examination were marked pallor, slight icterus of the sclerae, a smooth clean tongue, and malnutrition.

Laboratory Data—The peripheral blood revealed the presence of a macrocytic hyperchromic anemia. A bone marrow aspiration was compatible with pernicious anemia or sprue. The chest x-ray, a gastrointestinal series and the electrocardiogram disclosed no abnormalities. The urine showed a 1 plus test for albumin. The blood urea nitrogen was 15 mg, and the blood sugar, 115 mg per 100 milliliters. The value for total blood proteins was 6.7 Gm per 100 cc, with an A/G ratio of 2. The total blood cholesterol was 200 mg per 100 cc of which 35 per cent were esters. The icterus index was 7 and the van den Bergh

From the Medical Service of Dr. Thomas H. McGavack, Metropolitan Hospital, Welfare Island, N. Y.

Fig 7

reaction was negative. The cephalin flocculation was negative and the alkaline phosphatase was 1.9 units.

The patient was treated with a special experimental liver fraction without a clinical response. He was then given 10 mg of folic acid daily by mouth, this treatment was followed by an uneventful clinical and hematologic remission.

Initial red cell and mean corpuscular esterase values were in the normal range. The plasma esterase activity was about one-half the mean normal value. Following the injection of an experimental liver fraction there was definite but unsustained increase in erythrocyte cholinesterase activity. A subnormal reticulocytosis of 7.8 per cent was also noted. There was an equivocal transient rise in the red blood count. When all the values had returned to pretreatment levels, treatment with folic acid in daily oral doses of 10 mg was initiated. This

was followed by a rapid increase in all values except that of plasma cholinesterase, the latter did not change for sixteen days and then rose in a manner paralleling that of the red cell count

RESULTS

In ten patients with pernicious anemia in relapse the mean esterase activity of the red blood cells was 5.90×10^{10} units as compared with 7.55×10^{10} units in normal subjects. In four patients it was within the normal range of 6.19 to 8.69 ($\times 10^{10}$) units. The plasma levels were low with an average activity of 1.60 units as compared with 3.31 units in the normal. Eight of the plasma determinations in the patients with pernicious anemia were within the low normal range (Table I). Three to nine days after beginning effective anti-pernicious anemia therapy there was a rapid rise in red blood cell esterase. The red cell activity rose to above normal value, remained high for thirty-five to eighty-five days, and declined to the average range. The plasma esterase activity remained unchanged at the initial low levels and did not rise until eighteen to thirty days after the onset of effective therapy. The slope of the plasma rise tended to parallel the slope of the erythrocyte rise as both returned to normal.

Whole blood ChE cholinesterase activity in 1 ml of whole blood. Plasma ChE cholinesterase activity in 1 ml of plasma. RBC ChE cholinesterase activity in 1 ml of red blood cells. MCV mean corpuscular volume in cubic microns. Cell ChE mean corpuscular esterase activity in units per cell ($\times 10^9$).

There was no correlation between the initial red cell esterase activity, the red cell count, or the hemoglobin concentration. The mean corpuscular esterase was similarly unrelated to the mean corpuscular volume. There was an apparent relationship between the initial plasma esterase and the patient's general condition. The plasma esterase was not dependent, however, upon the initial red cell count or the hemoglobin concentration.

Following adequate antipernicious anemia therapy and in patients maintained on adequate therapy, the mean red cell enzyme activity was 8.31×10^{10} units (normal, 7.55×10^{10}). The plasma level in these patients was 2.63 as compared with 3.31 in normal subjects. The mean hemoglobin concentration was 14.0 Gm per 100 ml of blood, and the mean erythrocyte count was 4,600,000 per cmm (Table II).

Four patients (Cases 3, 5, 6, and 7) were given preliminary suboptimal therapy with either folie acid or experimental liver fractions of varying potency without causing a significant rise in the erythrocyte counts. In three of these patients (Cases 3, 5, and 7) small reticulocyte peaks of less than 8 per cent were observed nine, five, and six days, respectively, after injection of the extract. A rapid unsustained peak to normal values of the mean cell esterase was noted nine, four, and ten days, respectively, after the fraction was given. One patient (Case 6) had no reticulocytosis, and no effect on cholinesterase values was seen.

DISCUSSION

It would appear that in the normal individual the cholinesterase activity of the whole blood, red cells, and plasma remains constant within a narrow range from day to day and month to month.¹⁵ Patients with pernicious anemia in relapse exhibit low whole blood, red cell, and plasma esterase activity. When therapy is instituted the esterase activity of whole blood and red cells increases rapidly. This increase is shown to be due to an increase in the mean red cell esterase activity and does not reflect an erythrocyte rise which it invariably precedes. The plasma cholinesterase remains constant during this period. In four patients (Cases 1, 2, 3, and 7) the initial rapid red cell cholinesterase rise occurred at the same time that a reticulocytosis was noted. In cases 4 and 6 the reticulocytosis preceded the red cell esterase rise. In Case 5 the reticulocytosis continued even when the red cell esterase activity was falling. Where subeffective therapy was given, minimal reticulocytic response was associated with significant red cell esterase rise. Thus, a direct relationship between red cell esterase and reticulocytosis could not be established. In Cases 2, 3, 5, 6, and 7 the cell cholinesterase was not dependent on the mean cell volume. In two patients (Cases 1 and 4) the red cell esterase curves closely followed the curve of the mean cell volume.

Apparently patients with pernicious anemia in relapse have erythrocytes that are abnormally low in cholinesterase activity, and plasma that exhibits a subnormal esterase activity. The administration of liver extract or folie acid,

parenterally or orally, is immediately followed by an increase in the cholinesterase activity of the red cells. This increase is most frequently carried to levels greater than those found in the red cells of normal subjects. Following a variable period of time (about five to ten weeks) the red cell activity declines to and remains within the normal range. At this time a rise in plasma esterase is noted.

Sabine¹ postulated a normal mechanism for maintaining a high esterase in the mature cell of the anemic patient and the failure of the mechanism in the patient whose marrow is incapable of responding. She further postulated a specific defect in pernicious anemia with an "inability to put out cholinesterase in adequate amounts in such cells as the marrow produces." Davis^{10,11} believes that relapse in pernicious anemia is related to the increased activity of acetyl choline. He believes that this increased concentration produces a dilatation of the vascular network of the bone marrow with an increase in marrow oxygen tension. With this increase in oxygen tension an inhibition of the maturation of cells of the erythroid series occurs.

We have accumulated data¹² in various other anemias. It is our experience that pernicious anemia alone shows the consistently low cholinesterase activities we have described, with the possible exception of myeloid leucemia. Other anemias with similar low hemoglobin and erythrocyte counts are associated with normal or above normal red cell esterase activity. The plasma activity in these cases is dependent upon the patients' general condition being as low as or lower than the levels herein reported. Reticulocyte counts in these cases have revealed no consistent trend.

SUMMARY

Observations on seven patients with pernicious anemia in relapse are reported. The cholinesterase activity of whole blood red cells and plasma has been followed during their return to remission.

The cholinesterase activity of whole blood, red cells, and plasma in pernicious anemia patients in relapse is below normal levels.

With therapy, the cholinesterase activity of the red cell is the first to rise. This rise in activity is not related to the reticulocytosis; the mean cell volume or the increase in the number of red cells.

The plasma activity remains constant until the values for red cell esterase have become abnormally high and then have returned to normal levels.

The authors express their appreciation to Dr. Robert A. Lehman, Department of Therapeutics, New York University College of Medicine, for his many helpful criticisms and suggestion.

A STUDY OF CHOLINESTERASE ACTIVITY IN THE BLOOD OF NORMAL SUBJECTS

ARTHUR SAWITSKY, M D * HOWARD M FITCH, PH D, AND LEO M MEYER, M D
NEW YORK, N Y

DALL,¹ in 1914, postulated the presence of a blood esterase which would inactivate acetylcholine. Loewi, working with the isolated frog heart, demonstrated that stimulation of the vagus liberated a substance which itself was capable of producing the effect previously thought to be due to action of the nerve. Loewi and Naviatil² showed that this vagus substance was an ester of choline, probably acetylcholine. These authors also found that aqueous extracts of frog heart inactivated acetylcholine. Because these extracts acted in an enzyme-like manner, they called the active principle an esterase. In 1930 Engelhart and Loewi³ and, independently, Matthes⁴ conclusively demonstrated the enzymic nature of the distinctive agent. Three years later, Stedman, Stedman, and Larson⁵ presented evidence of the presence of cholinesterase in the blood serum of the horse. In 1935, Stedman and Stedman reported that sera from different species differed widely with respect to the content of cholinesterase. These authors found that the erythrocytes of various species of animals also contained appreciable amounts of enzyme. By this time a host of papers had appeared and various phases and characteristics of the enzyme were reported in the literature. Almost all of the earlier work was based on the enzyme present in serum or plasma.

Plattner and Gilchi,⁶ using a biologic assay method, found that the cholinesterase activity of erythrocytes was greater than that of serum. Matthes confirmed this finding. Stedman and Stedman showed in a series of experiments using a physicochemical technique that sera of different species differed widely with respect to the cholinesterase content and that the erythrocytes of various species contained appreciable amounts of enzyme. Hall and Lucas⁷ studied normal and pathologic human sera and concluded that age, sex, activity, diet, heart rate, and blood pressure were without influence on the serum esterase. They reported that the range of serum esterase values for any individual was constant, but that this might vary widely from individual to individual. In 1940, Sabine¹⁰ showed that the cholinesterase activity of erythrocytes was greater than that of plasma in both normal and pathologic subjects. Alles and Hawes¹¹ confirmed her findings.

Brauer and Root¹² recently demonstrated a correlation between liver cholinesterase and the serum esterase of the dog. Similarly, it has been shown¹³ that the rate of human serum esterase regeneration is significantly lower in patients with liver disease than in the normal subject. Cohn and co-workers¹⁴ have found that plasma esterase activity is largely concentrated in plasma fraction IV 4. This plasma fraction is rich in alpha and beta globulins of low lipid

content Mendel and associates,^{15, 16} on the basis of substrate concentrations and substrate specificity, postulate two different cholinesterases in the body—one a specific of true esterase found in red blood cells and brain tissue, the other a nonspecific or pseudoesterase found in serum and plasma Nachmansohn and Rothenberg^{17, 18} have inclined toward the view that specificity is relative and that tissues containing the specific esterase split acetylcholine at a higher rate than they split other esters Bodansky¹⁹ speaks of a "family" of cholinesterases whose members resemble one another in some characteristics and differ in others Thus, within one species the enzyme differs in certain respects from tissue to tissue, and in a given tissue, from species to species

METHODS

The plasma and red cell cholinesterase activities of random blood samples taken from nine male and six female subjects were determined Serial samples were tested at monthly intervals in three of these subjects Oxalated venous blood was drawn from a vein in the antecubital fossa The hematocrit (Wintrobe) was determined and the samples separated into whole blood and plasma A complete capillary blood count was done at this time Random reticulocyte counts were done in five subjects

The cholinesterase activity was measured in units representing the number of milliliters of 0.02N sodium hydroxide necessary to neutralize the acetic acid liberated from 100 ml of 0.012M acetylcholine bromide solution by 1 ml of whole blood or plasma in a twenty minute period at a pH of 7.4 ± 0.05 The temperature was held constant at 37.5°C Red cell esterase activity was calculated from the whole blood activity, plasma activity, and the hematocrit value A correction factor applied to all esterase values was derived from a determination of the amount of acetylcholine hydrolyzed under the same conditions in the absence of blood The mean corpuscular esterase was calculated by multiplying the red cell esterase activity by the mean corpuscular volume

$$\text{Mean cell ChE} = \text{Red Cell ChE} \times \text{MCV}$$

$$\text{Units/cell} = \text{Units/ml} \times \text{ml/cell}$$

The cholinesterase activity of 1 ml of red blood cells ranged from 7.25 to 10.34 units, with a mean value of 8.76 units. The mean corpuscular esterase activity varied from 6.19 to 8.69 units ($\times 10^{10}$), with a mean value of 7.55 units ($\times 10^{10}$). The esterase activity of 1 ml of plasma was found to be 1.50 to 5.00 units, with a mean of 3.19 units. Activity did not seem to be influenced by sex. Although the activity varied markedly from individual to individual, within the same subject the activity remained rather constant (see Table II).

SUMMARY

Our results confirm the findings of previous workers that in the human subject cholinesterase activity of the red blood cell is greater than that of the plasma. The cholinesterase activity may vary widely from individual to individual, but tends to remain fairly constant in any one individual.

A COMPARISON OF METHODS USED FOR THE HYDROLYSIS OF CONJUGATED URINARY ESTROGENS

JOHN T. VAN BRUGEN, PH.D.*

St. Louis, Mo

A PREVIOUS report from this laboratory suggested the need for a thorough study of the methods for the hydrolysis of urinary estrogens. Gallagher¹ has reviewed a number of the factors concerned in urine hydrolysis and has pointed out that present methods are not entirely satisfactory.

In addition, the fact that most methods of urine hydrolysis have established definite time intervals of treatment indicates that acid hydrolysis of urine may be, in reality, a balance between two simultaneous reactions namely, hydrolysis and destruction. The method giving the greatest yield of free forms, then, would be one which caused the hydrolysis of a maximum amount of conjugated forms while the destructive process was kept at a minimum. The mechanics of the reactions that cause a decrease in biologic activity of estrogen preparations subjected to acid hydrolysis are as yet unknown. Pincus and Pearlman¹¹ have reviewed the subject of artifacts arising from the acid treatment of androgen preparations and they point out the misconceptions that may arise from such procedures.

Good yields of free estrogens were obtained by Cohen and Marrian by adjusting the pH of the urine to 1.0 with HCl, further acidifying with 3.3 ml of 12 N HCl per 100 ml urine, and finally, heating the sample at 120° C. for two hours. Smith and Smith¹ advocated the use of reflux hydrolysis for ten minutes of urine samples made to 15 volumes per cent with HCl and found good agreement between their method and the Cohen and Marrian procedure. Dingemans, Laqueur, and Muhlbock⁴ hydrolyzed urine with 15 ml of 25 per cent HCl per 100 ml urine and at the same time extracted freed forms with a layer of benzene. Three four hour periods of boiling with a total of 150 ml of organic solvent were used.

Other methods of treatment have been suggested^{3, 8, 9, 13} but because of difficulties of too mild or too drastic conditions have not been adopted generally.

Leiboff and Tamis,⁹ Smith and Smith¹² and Gallagher, Peterson, Dorfman, Kenyon, and Koch⁶ have used continuous extraction equipment for the extraction of hydrolyzed urine. Talbot, Butler, MacLachlan, and Jones¹⁵ reported a procedure for the simultaneous hydrolysis and extraction of urinary 17 ketosteroids.

Before urine hydrolysis studies were undertaken the effect of hydrolysis conditions on pure estrogens was ascertained.

This work is admittedly incomplete but since it is not possible to continue the investigation at this time these results are being published in the hope that they may be of interest to investigators in the field.

From the Department of Biochemistry, St. Louis University School of Medicine.

Received for publication, Nov. 3, 1947.

Effect of Acid Hydrolysis on Free Estrogens—Smith and Smith¹⁴ found there was no loss of activity of estione, estriol, or α -estradiol when solutions of these forms were treated by their hydrolysis conditions, namely 100° C for ten minutes with 15 volumes per cent HCl, but they found there was an appreciable destruction of estione by heating at 100° C for twenty minutes with 15 volumes per cent HCl.

We have confirmed the observation that prolonged boiling of pure estrogens in 15 volumes per cent HCl causes destruction. Thirty minutes of boiling of pure estrogens in distilled water made 1.6 N with HCl caused 28 per cent destruction of estriol, 34 per cent of estione, and 34 per cent of α -estradiol. As previously reported,⁵ no destruction of activity occurred when pure estrogens were hydrolyzed in an atmosphere of nitrogen and in the presence of a protective agent (1-amino-2-naphthol-4-sulfonic acid). Residual estrogenic activity was determined by bio-assay, for colorimetric determinations on these same fractions showed a wide discrepancy from bio-assay results.

Hydrolysis of Known Conjugated Estrogen—The principal estrogen conjugate in human urine appears to be estriol glucuronide. Although estrone also may be excreted in a conjugated form (perhaps as the sulfate, as in male urine), such a compound has not been isolated from human sources.

The conditions affecting hydrolysis of the pure estriol conjugate have not been reported previously. We have studied the behavior of this compound under three conditions listed below. Aliquots of standard solutions of sodium estriol glucuronate* were added to distilled water and further treated in the following manner. The first sample was adjusted to a pH of 1.0 with HCl and allowed to stand at room temperature for ten days. Such treatment liberated only 5 per cent of the combined form. The second sample was hydrolyzed for ten minutes at 100° C with 15 volumes per cent HCl, under N₂ and in the presence of the previously described protective agent, and gave 99 per cent hydrolysis. The third preparation was treated like the second except that only enough HCl was added to make the solution 0.1 N. In this case only 20 per cent of the estriol was liberated.

The second and third samples show the importance of acid concentration and the necessity of heat treatment and also indicate that the acid and heat treatment of the Smith and Smith¹² procedure are effective hydrolytic agents for this conjugate in pure solution.

Hydrolysis of Pregnancy Urine—Preliminary studies on each of five urines obtained during the fifth and sixth month of pregnancy indicated a considerable variation in results. The Smith hydrolysis and our protective hydrolysis modification of the Smith method were the chief methods employed. These studies indicated that nitrogen and the protective agent in a few cases gave higher amounts of freed estrogens. As Doisy has previously reported,⁶ in one of the urines tried, the potency of an aliquot of a twenty-four hour specimen was doubled as the time of hydrolysis was increased from ten minutes to forty-five minutes.

*Obtained through the kindness of A. S. Cook of Averst McKenna and Harrison Montreal, Canada.

To minimize the possible variations given by single isolated specimens and to insure an adequate supply of urine for future work an 18 liter sample of pregnancy urine was collected by pooling twenty four hour urine specimens from patients seven months pregnant. This pooled urine was preserved with chloroform, the pH adjusted to 7.0, and the urine filtered and stored at 3 to 5° C. The experiments to be described represent a comparison of a number of techniques all carried out on aliquots of this stool urine.

Bio assay, by a modified Marrian and Parker method recently described by Thayer, Doisy, Jr, and Doisy¹⁶ was conducted on all estrogenic fractions.

After preliminary assays had determined the proper dose level, the final assays of an experiment were run on a group of animals available on a single assay day. A minimum of twenty animals was used at each assay level and twenty animals served as controls. Although great care was taken in these bio assays it must be kept in mind that differences in results of 20 per cent probably are not significant.

The yield of estrogen obtained in each of the experiments indicated that although ether extracts of hydrolyzed urines were further separated into phenolic, nophenolic, and acidic fractions, colorimetric analysis by a modified sulfanilic acid method (Van Bruggen¹⁷) and by Baehman's method¹ gave results that differed markedly from the bio assay results. Although a few such chemical determinations gave good agreement with bio assay figures, for the most part the colorimetric determinations gave values from two to eight times higher than bio assays.

Preliminary studies indicated that the ten minute hydrolysis with 15 volumes per cent did not give complete hydrolysis of combined forms. To test this possibility, several experiments were carried out.

Experiments 1 and 2—Of the 18 liter pooled sample, 1,200 ml were acidified to 15 volumes per cent with HCl and refluxed in an all glass apparatus fitted with a siphon. This arrangement permitted the withdrawal of samples of the boiling urine at various time intervals. One hundred fifteen milliter samples were withdrawn, cooled under water, and saturated with NaCl to help prevent emulsion formation. The estrogens were extracted from the treated urine with four 50 ml portions of purified ethyl ether. The combined ether extracts were washed with 9 per cent NaHCO₃, dilute HCl and distilled water. The ether was removed by distillation and the residue taken up in 95 per cent ethanol. The zero hour sample was taken after acidification but before the system was heated and should thus represent free estrogens present. A similar experiment was carried out but differed from the first in that 125 mg of 1 amino 2 naphthol 4 sulfonic acid per 100 ml urine were added to the urine. In addition N was passed through the urine for a ten minute period before heating was started as well as during the hydrolysis. Table I lists the data obtained from these two experiments.

Experiment 3—In this experiment the method of Marrian² and several modifications of his method were studied. Three 100 ml aliquots of the pooled urine were adjusted to a pH of 1.0 with HCl. To one of these an additional

10	240	-----	50,000

1 ml of concentrated HCl was added, to the other two, 3 ml additional HCl were added. One of these two also received a small amount of the protective agent. Two other 100 ml samples were adjusted to a pH of 1.00 with H_2SO_4 . One of these received an additional 1 ml of concentrated H_2SO_4 , the other, 3 ml of H_2SO_4 . The five flasks were then simultaneously autoclaved at 120° C for two hours. After this pressure hydrolysis, the samples were cooled and extracted by the technique mentioned in Experiment 1. Table II compares the results of the experiment on the five samples.

TABLE II TWO HOUR PRESSURE HYDROLYSIS AT 120° C OF ALIQUOTS OF THE POOLED URINE, ALL SAMPLES BEING FIRST ADJUSTED TO pH 1.0 WITH THE APPROPRIATE ACID

SAMPLE	ADDITIONAL TREATMENT	M U PER LITER
1	1 ml HCl per 100 ml urine	116,880
2	3 ml HCl per 100 ml urine	123,750
3	3 ml HCl per 100 ml urine plus protective agent	132,000
4	1 ml H_2SO_4 per 100 ml urine	86,663
5	3 ml H_2SO_4 per 100 ml urine	103,120

Experiment 4—The high activity of fractions 4-A and 7-B of Experiments 1 and 2 (Table I) after the ten-minute time as well as the good yield of the third fraction (Table III) suggested that the ten-minute hydrolysis with 15 volumes per cent HCl was not liberating all of the combined estrogens. This experiment was devised to determine the degree of hydrolysis effected by the Smith¹² method as performed in our experiments. One liter of the pooled urine was made acid to 15 volumes per cent with HCl and heated in the same apparatus used in Experiments 1 and 2. Samples were taken and extracted four

TABLE III PRELIMINARY HYDROLYSIS AND EXTRACTION (COLUMN A) AND SUBSEQUENT RECOVERY OF ESTROGENS BY HYDROLYSIS AND EXTRACTION (COLUMN B)

SAMPLE	TIME OF HYDROLYSIS OF FIRST SAMPLE (A)	M U PER LITER		TOTAL RECOVERY (A PLUS B)
		A	B

6	120	89,375	1,200	90,575

times with ether as before. However, after free estrogens had been extracted with ether, the urine residue was thoroughly extracted with butyl alcohol to remove conjugated forms. The butyl alcohol was concentrated, the residue dissolved in 100 ml water, HCl was added to 15 volumes per cent, and the extract hydrolyzed for ten minutes, the estrogens were removed with ether as before. Each extract was assayed separately. In Table III, column A represents the activity obtained by the first hydrolysis and column B represents activity present in the hydrolyzate of the butanol extractions. Activity in B, then, represents estrogens not hydrolyzed or extracted by a simple acid hydrolysis.

Experiment 5—The high activity of the B fraction of the ten minute hydrolysis of the previous experiment might be due to one or both of two factors. Although the distribution coefficient of an acid ether partition strongly favors the movement of estrogens into the organic phase, it is possible that faulty extraction of the urine might account for the activity of the B fraction. On the other hand, incomplete hydrolysis at ten minutes might cause the retention of activity in the water phase. The following data were obtained in an effort to clear up this matter. An aliquot of the pooled urine was hydrolyzed for ten minutes with 15 volumes per cent HCl. After the customary ether extraction, the urine residue was extracted with butanol. The butanol extract was divided into two equal parts, one half of which was concentrated at a low temperature under suction to avoid hydrolysis during this time. The other half of the butanol extract was concentrated and rehydrolyzed as in Experiment 3. This fraction then contains the ether soluble estrogens after hydrolysis of the butanol extract. In the original ether extract 103,100 M U per liter were found, 6,000 M U per liter were found in the butanol extract that was not rehydrolyzed. The butanol fraction that was rehydrolyzed showed 15,000 M U per liter.

The effectiveness of continuous extraction and hydrolysis was studied in a number of experiments. It was felt that if the free estrogens could be extracted by an organic solvent immediately after their release from the conjugate form, that destruction might be minimized. Attempts to accomplish this by a number of methods are reported below.

Experiment 6—One hundred milliliter samples of the pooled urine were made to 15 volumes per cent HCl and were then layered with 100 ml amounts of toluene, butanol, benzene, and cyclohexanol, respectively. Such systems were boiled under reflux for two hours. During the heating period, good contact between the urine and the organic solvent was assured by the bubbling of a stream of nitrogen through the solutions. After the two hour heating the urine and solvent were cooled the organic solvent layer removed, and the urine residue further extracted with three additional portions of the same solvent used during the heating period. Toluene gave a recovery of 41,300 M U per liter, butanol, 82,500, benzene, 64,800, and cyclohexanol, 70,000.

Experiment 7—Since the original hydrolysis and extraction described by Dingemans and co workers' was for a considerably longer period of time, and used, in addition, a greater total amount of solvent, the procedure of Experiment 6 was not comparable. To approximate the conditions used by Dingemans

manse, 100 ml of urine were acidified with 23 ml HCl, the urine covered with 100 ml benzene, and the mixture refluxed for four hours. The benzene was removed and replaced with 100 ml fresh solvent and the urine and benzene again refluxed. A third such treatment gave a total of 300 ml benzene used during a total hydrolysis and extraction period of twelve hours. The benzene solutions were combined, washed with a small amount of water, and taken to dryness. By this method, a total of 500,000 M U per liter was obtained.

Experiment 8—The principle of the previously mentioned continuous hydrolysis and extraction procedure of Talbot and associates¹⁵ was applied to our problem of estrogen recovery. The apparatus used was similar in construction to that described by Smith and Smith.¹² The lighter-than-water solvents used were delivered to the bottom of the urine phase by a tube having a porous glass disk at the bottom. The column of urine was surrounded, in addition, by a water bath that permitted the maintenance of the urine at elevated temperatures. With benzene as the circulating solvent, the urine was kept at 70° C and 77,000 M U per liter were obtained, with toluene the temperature was 80° C, 77,000 M U per liter being found, and cyclohexanol permitted a temperature of 90° C with a recovery of 100,000 M U per liter.

TABLE IV HYDROLYSIS OF CONJUGATED ESTROGEN IN BUTYL ALCOHOL

SAMPLE	TIME OF HEATING	M U PER LITER
1	0	74,250
2	10	107,250
3	60	103,125
4	120	148,500

Experiment 9—Liquid ammonia has within recent years been extensively employed in organic hydrolysis procedures. Hydrolysis with liquid ammonia (ammonolysis) was attempted in two ways. In Experiment 9a the total estrogens were extracted from urine with butanol. After the butanol was evaporated, the residue was taken up in 20 ml dry butanol and 40 ml liquid ammonia were added. The mixture (in an open glass tube) was enclosed in a bomb made of two-inch steel pipe capped at each end by ordinary pipe caps. After forty-eight hours at room temperature the residue was distilled to dryness and taken up in 95 per cent ethanol as usual. In Experiment 9b, a butanol extract of urine was taken to dryness, the residue transferred to the glass inner tube of the bomb, and the dry residue treated with liquid ammonia. A total of 48,125 M U per liter was obtained by the first treatment and 68,750 M U were obtained by the second method.

Experiment 10—It was thought that if the total estrogens could be removed from the urine and the combined forms then hydrolyzed, that destruction might be reduced. To this end, 500 ml of the pooled urine were made acid to congo red and extracted with five 100 ml portions of butyl alcohol. The combined butanol extracts were washed once with water, made to 15 volumes per cent with HCl and hydrolyzed as in Experiment 1. One hundred thirty milliliter samples were withdrawn (equivalent to 100 ml urine), cooled,

and concentrated alkali added until the aqueous phase which separated was just acid to litmus. The alcohol was concentrated and the residue taken up in ethanol.

Table IV gives the results of the previously described experiments in terms of mouse units per liter of urine.

DISCUSSION

In discussing the results of these experiments it should be kept in mind that the yields by the various techniques have been obtained by bio assay and that differences of 20 per cent are not significant. Experiment 1 bears out the previous suggestion that at least with the pooled urine used in this work a ten minute hydrolysis with 15 volumes per cent HCl does not hydrolyze all the conjugated forms present. Since boiling for periods greater than twenty to thirty minutes in 1.6 N HCl is known to destroy estrogens it seems likely that the high activity present at forty minutes is due to the presence of a hydrolytic process and its predominance over a destructive process. There seems to be little advantage to using nitrobenzene and the sulfonic acid as in Experiment 2 although experiments on pure estrogens had demonstrated the effective protection of such treatment.

The data of Experiment 3 indicate that pressure hydrolysis is an effective method for urine hydrolysis. Protection of labile forms by the mild reducing agent was of definite value in this procedure. The good recovery of activity by the pressure hydrolysis method recommends it for a routine procedure.

Experiment 4 bears out the previous contention that in this work the ten minute hydrolysis with 15 volumes per cent HCl does not give a quantitative yield of estrogens. The total of 93,000 units of the zero hour sample closely approximates the 95,000 units given by the regular ten minute hydrolysis of the ten minute sample. The 31,250 units of the rehydrolyzed specimen of the ten minute sample, however, represent approximately a 25 per cent potential loss when the routine Smith¹ method is used. The activity of the rehydrolyzed specimens even up to 120 minutes might indicate the presence of some difficulty hydrolyzable or extractable form in pregnancy urine.

That the usual four extractions with ether may not remove all the supposedly ether soluble forms is indicated by Experiment 5. The 6,000 units not extracted by the ether represent 5 per cent of the total activity potentially lost while the sum of the second and third fractions (21,000 units) represents a 17 per cent over all loss.

The protection offered by the layering used in Experiment 6 does not appear to have been outstanding. It is possible that better yields might have been obtained if shorter periods of heating had been used. In these four samples the good yield by the use of butanol is in agreement with the results obtained in Experiment 10.

The low recovery of activity seen in Experiment 7 is probably due to the excessively long heating period used. The acid concentration used was somewhat greater than that recommended by Dingemans⁴ so that the method is not exactly as described by that author.

The use of continuous hydrolysis and extraction as in Experiment 8 seems to be of promise, however, the high boiling point (161.5°C) of the cyclohexanol makes it undesirable as a routine solvent. Somewhat different periods of heating and temperature conditions might greatly improve this procedure.

Liquid ammonia as used in Experiment 9 did not cause appreciable hydrolysis of conjugated forms. A more refined bomb container which would allow the retention of higher pressure might greatly enhance the utility of this method.

The use of butanol as the solvent and hydrolyzing medium, as in the final experiment, appears to be of definite promise. Woolf, Viergiver, and Allen¹⁸ have shown that the method of extraction used in this experiment would quantitatively extract all the pregnandiol glucuronide so that it is probable that most of the estriol complex was removed. The 74,000 units of the zero hour sample probably represent some hydrolysis of conjugated forms during the removal of the butyl alcohol from the sample. The 148,000 units present in the two-hour fraction were the highest yield obtained in these studies.

SUMMARY

A number of factors affecting the hydrolysis and extraction of urinary estrogens have been investigated. The use of 15 volumes per cent HCl for ten minutes as the hydrolyzing medium, although giving reasonably good results, does not appear to give optimum yields. Pressure hydrolysis under conditions similar to those advocated by Cohen and Marrian² is of definite advantage. The hydrolysis of combined forms in an organic solvent (butanol) gave the highest yields obtained. Preliminary work indicated that there might be wide differences in individual samples of urine, the use of a pooled sample presumably nullified these individual differences. It is possible that if studies such as have been presented in this paper were complemented by a fractional analysis of all urine samples, considerable light could be thrown on the hydrolysis and destructive reactions.

STUDIES ON THE CHEMOTHERAPY OF FILARIASIS

VI SOME PHARMACODYNAMIC PROPERTIES OF 1-DIETHYLCARBAMYL-4-METHYLPIPERAZINE HYDROCHLORIDE, HETRAZAN

B K HARNED, RAYMOND W CUNNINGHAM, SYBELLA HALLIDAY, R E VESSEL,
N N YUDA, MARY C CLARK, CAROLYN H HINE, RACHEL COSGROVE, AND
Y SUBBAROW
PEARL RIVER, N Y

THE introduction by Hewitt and co-workers^{1, 2} of 1-diethylcarbamy-4-methyl piperazine hydrochloride as a filaricide effective in experimental animals and in man has necessitated an investigation of the pharmacologic properties of this compound. The use of piperazines in medicine is not new. For more than a decade prior to 1918³ piperazine and 3,6-dimethylpiperazine were accepted remedies for the treatment of gout and rheumatism. Although these drugs were worthless in these diseases,^{3, 4} the years of use served to establish the low toxicity of the nucleus and to provide excellent descriptions of the symptoms of over dosage.

1-Diethylcarbamy-4-methylpiperazine hydrochloride, also referred to as Hetrazan and 84-L, has a molecular weight of 234.6⁵ and has the following structural formula:

It is a colorless crystalline solid, highly soluble in water, alcohol, and chloroform, but insoluble in benzene, ether, and petroleum ether. The pH of a 10 per cent solution is 4.1. In the pharmacologic experiments the solutions were adjusted to pH 7.4.

METHODS

The acute toxicity of single doses was studied in six species. Multiple doses at short intervals were given to mice, rats, and dogs. Studies on the chronic toxicity were made with rats, rabbits, dogs, and chickens.

Tests for irritation were made by intracutaneous injections in guinea pigs of 0.1 cc of 10 per cent solutions and by local application of the same concentration to the eyes of cats. Antihistaminic action was tested on the isolated guinea pig gut and on guinea pigs in a spray chamber. Cats were used for pupillary studies. Hemoglobin was determined as cyanmethemoglobin.⁶ The Lapschutz assay⁷ was used to evaluate diuretic action. Analgesia was determined by a method which employed the application of heat to the rat's foot.⁸

From Lederle Laboratories Division, American Cyanamid Co.
Received for publication Nov. 17, 1947.

Respiratory movements were relayed to a kymograph by a string attached halfway between the inferior end of the sternum and the umbilicus. Electrocardiographic studies were made with a Cardiotron on anesthetized and unanesthetized dogs. In anesthetized animals blood pressure was recorded from the carotid artery. In unanesthetized dogs the pressures were recorded by femoral arterial puncture.

RESULTS

ACUTE TOXICITY —

Single Doses —

Mice and Rats The dose mortality curves recorded in Fig 1 summarize the data from 238 mice and 260 rats. Toxic doses produced convulsions that were predominately tonic. The convulsant dose however was considerably below the fatal dose.

ACUTE TOXICITY OF 1 DIETHYL CARBAMYL 4 METHYL PIPERAZINE HYDROCHLORIDE (84L)

Fig 1—The experimental results were plotted on log probability paper* and straight lines were fitted by eye. The 19/20 fiducial zones were estimated by a modification of the method of Litchfield and Fertig.⁶ The modification allowed for the fact that the population was not homogeneous in all cases and consisted of correcting the estimated values by multiplying

by $\sqrt{\frac{(Chi)}{n}}$ as described by Wilcoxon and McCallan.⁷

Guinea Pigs, Rabbits, Cats, and Dogs Lethal doses were not determined in these species but large doses were tolerated with few signs of toxicity. Ten guinea pigs given 50 mg per kilogram intraperitoneally showed no changes. Objectionable reactions were not observed in fifteen rabbits given 100 mg per kilogram by the same route. Twenty five milligrams per kilogram given intra

peritoneally to six cats and 50 mg per kilogram given to three cats caused vomiting in six to ten minutes. In addition, these animals showed slight drowsiness.

Serious reactions were not observed in unanesthetized dogs that had received 100 mg per kilogram orally or intraperitoneally or one-fifth of this dose by rapid intravenous injection. If reactions occurred they were, in order of frequency, nausea, vomiting, and muscular tremors. The tremors closely approximated those of a dog shivering from a low temperature. In addition to these reactions, intravenous injections caused stimulation of the respiration which lasted from one to three minutes (Fig 3). Oral doses of 50 mg or more per kilogram often produced emesis, but the presence of food in the stomach decreased the frequency of this occurrence. Oral doses of 25 mg per kilogram administered with food usually were retained.¹ Table I contains the data on thirty-nine dogs.

TABLE I REACTIONS OF UNANESTHETIZED DOGS TO HETRAZAN (84 L)

NUMBER OF DOGS	DOSE (MG/KG)	ROUTE OF ADMINISTRATION	SYMPTOMS			
			NAUSEA	EMESIS	RESPIRATORY STIMULATION	SHIVERING
			INCIDENCE IN PER CENT			
11	5	Intravenous†	9	9	100	0
2	10	Intravenous†	0	0	100	0
4	20	Intravenous†	75	50	100	0
1	25	Intravenous†	100	0	100	100
1	50	Intravenous†	100	100	100	100§
2*	100	Intraperitoneal	100	100		100
5	50	Oral†	80	60		20
12	100	Oral†	66	66		8
1	200	Oral†	100			100

Respiratory stimulation lasted about one minute. Shivering lasted from thirty to sixty minutes. Vomiting never was accompanied by continued retching or signs of malaise. Recovery was excellent in all dogs.

*These dogs were given 100 mg per kilogram twice daily for two days.

†The intravenous injections were completed within one minute.

‡Dogs were fed two to five hours before dosing.

§Severe muscular tremors.

Repeated Doses —

Since the antifilarial data of Hewitt and associates¹ indicated the necessity for frequent administration of Hetrazan it seemed desirable to study the rate of its destruction or excretion. For this study experiments were designed to give rats and mice repeated injections at a rate which barely exceeded the capacity of the animal to eliminate the compound. The criteria of accumulation were the incidence of convulsions and the percentage of mortality.

In rats the intraperitoneal LD₅₀ is 465 mg per kilogram (Fig 1), therefore, in the tolerance studies a single intraperitoneal dose of 300 mg per kilogram was given at zero time, with additional doses of 100 mg per kilogram at hours 2, 3, 4, 5, 6, 7, and 8. The incidence of convulsions provided a delicate indicator of the rate of elimination of the compound (Table II). At 300 mg per kilogram 100 per cent of the animals convulsed, but after an interval of two hours an additional dose of 100 mg per kilogram produced no convulsions.

The incidence of convulsions after the third and fourth doses was 9 per cent in each case and after the eighth dose, 45 per cent. Although the total dose given to these rats amounted to 1,000 mg per kilogram, no increment subsequent to the initial dose produced convulsions in all rats. In three groups of rats, sixty-five animals, 300 mg per kilogram never failed to produce convulsions. Thus it appears that under the foregoing conditions the rat is capable of eliminating approximately 100 mg per kilogram per hour.

TABLE II THE EFFECTS ON RATS OF MULTIPLE INTRAPERITONEAL DOSES OF 84 L REPEATED AT SHORT INTERVALS

INTERVAL SUBSEQUENT TO INITIAL DOSE (hours)	NUMBER OF RATS INJECTED	DOSE		INCIDENCE OF CONVULSIONS (%)	MORTALITY (%)
		SINGLE (mg/kg)	CUMULATIVE (mg/kg)

*The survivors were divided into two groups I and II

†Combined results of a group of 10 and a group of 12 rats dosed on different days.

‡Twenty-four hours later all animals were in good condition

Obviously the validity of this calculation rests on the assumption that the rat does not become resistant to the convulsant action of the compound. This question has been answered by the data on Group II in Table II. In this series the original dose of 300 mg per kilogram was repeated after four hours. The incidence of convulsions was again 100 per cent and the mortality, 22 per cent. When additional doses of 150 mg per kilogram per hour were given on the fifth, sixth, and seventh hours, the incidence of convulsions rose from 43 per cent on the fifth hour to 71 per cent on the seventh. These data show that rats do not become resistant to the convulsant action of 84 L and also that 150 mg per kilogram per hour exceed the ability of the rat to eliminate the compound.

In Group I, Table II, the mortality from the initial dose of 300 mg per kilogram was 31 per cent, and from the succeeding doses, 700 mg per kilogram in six hours, 5 per cent. A similar experiment on mice has yielded data of the same order. Thus the administration of four times the LD₅₀ over a period of eight hours produced a total mortality of 27 per cent (Table III). The rate of elimination in milligrams per kilogram per hour appeared to be greater in mice than in rats.

TABLE III THE EFFECTS ON MICE OF MULTIPLE INTRAPERITONEAL DOSES OF 84-L RELATED AT SHORT INTERVALS

INTERVAL SUBSEQUENT TO INITIAL DOSE (HOURS)	NUMBER OF MICE INJECTED	DOSE		MORTALITY	
		SINGLE (MG/KG)	CUMULATIVE (MG/KG)	PER DOSE (%)	CUMULATIVE (%)

72	--	--	1350	0	70.0

*Twenty minutes after dose

†Since death from 84-L usually occurs within thirty minutes after the injection one hesitates to attribute this mortality to the pharmacologic action of the compound. However these figures do not affect the conclusions since 310 mg per kilogram in a single dose produced a mortality of 99 per cent.

Etherized dogs tolerated 60 to 70 mg per kilogram of 84-L given intravenously during a period of one hour. Dog 548 readily tolerated nine doses, each dose 5 mg per kilogram, during a period of ninety minutes (Fig 4) and Dogs 546 and 547 each received seventeen such doses in eighty minutes without endangering the respiration. Dog 549 (Fig 4) tolerated seven doses of 10 mg per kilogram during a period of sixty minutes but developed respiratory failure when the eighth dose was given on the seventieth minute. This dog was maintained without difficulty on artificial respiration. Dog 540 received four doses of 20 mg per kilogram during forty minutes. The fifth dose, which brought the total to 100 mg per kilogram in fifty-two minutes, produced respiratory failure. Artificial respiration maintained this animal in a satisfactory condition and twenty minutes after the fifth dose another injection of 20 mg per kilogram was made without producing encephalatory failure.

Unanesthetized dogs have been given 100 mg per kilogram intraperitoneally twice daily for two days without producing signs of toxicity more severe than vomiting and mild muscular tremors (Table I). One hour after the injections the animals appeared normal.

Chronic Toxicity—

Rats—The intraperitoneal injection of 100 mg of 84-L per kilogram five days per week for fourteen weeks did not affect the rate of growth or produce any unfavorable reactions in male rats (Fig 2). The control and dosed groups each started with twenty animals. After fourteen weeks there were fifteen in the control and fourteen in the dosed group. At the end of the series of doses the mean hematologic findings on ten rats from each group were: (1) hemoglobin, grams per 100 cc—control, 13.1, dosed, 13.5, (2) red blood cells, millions per cubic millimeter—control, 8.3, dosed, 8.7, (3) white blood cells, thousands per cubic millimeter—control, 14.4, dosed, 19.3, (4) lymphocytes, per

cent control, 61, dosed, 79, (5) neutrophils, per cent control, 34, dosed, 19, (6) eosinophils, per cent control, 37, dosed, 10 The pathologist* reported that no differences between the groups were found on examination of the tissues of the animals

Rabbits—Fifteen rabbits were given intraperitoneally, 50 mg per kilo gram of the drug for fourteen weeks The growth of the group was not significantly modified (Fig 2) During the period four animals died in the control

Fig 2

NUMBER OF ANIMALS	START	END
Control rabbits	1	11
Dosed rabbits	15	8
Control rats	20	15
Dosed rats	0	14

group and seven in the dosed but the distribution of deaths does not suggest that they were due to chronic effects of the drug After sixty six doses during ninety eight days the hematologic data revealed no difference between the control and the dosed groups The average results for the groups were (1) hemoglobin, grams per 100 cc control 11.1 dosed, 11.0, (2) red blood cells millions per cubic millimeter control 6.1 dosed 5.8 (3) white blood cells thousands per cubic millimeter control 8.6 dosed 10.3 (4) lymphocytes, per cent control, 69 dosed 70 (5) neutrophils per cent control 28 dosed 26

Dr F I Dessau Lederle Laboratories Division American Cyanamid Co made the examinations

Dogs—In a large series of dogs, Hewitt and associates¹ observed no evidence of chronic toxicity. Five of the dogs were given 50 mg per kilogram intraperitoneally twice a day for thirteen days and two were dosed orally with 25 mg per kilogram three times a day for sixty-four days. At the end of the period of dosing they were sacrificed and examined for pathologic changes,* but none were found that could be attributed to the treatment given.

Chicks—Robbins' observation¹¹ that 2,4-dinitrophenol produced cataracts in the eyes of chicks prompted us to subject 84-L to a similar test. A group of eighteen 8-day-old White Rock chicks was divided into three balanced groups. Group 1 received a diet which contained 0.25 per cent 84-L and Group 2, 0.25 per cent 2,4-dinitrophenol, Group 3 was given the basal diet. Chicks on 2,4-dinitrophenol developed cataracts during the first twenty-four hours. The chicks in Group 1 were continued on the 84-L diet for fifteen days and there was never any evidence of lenticular changes. At the end of the experiment the lenses were sectioned and examined by a pathologist,† it was reported that the lenses were normal. The chicks fed 84-L grew at the same rate as the control animals in Group 3, and in appearance the individuals of the two groups were indistinguishable.

MISCELLANEOUS OBSERVATIONS —

General Behavior Intraperitoneal doses of 50 mg per kilogram given to dogs, cats, rats, and rabbits produced few signs. The dogs and rats were more sensitive to loud noises, but thirty minutes after the injections many of the animals in all the species tested appeared to be more quiet than usual, however, they were not asleep and responded normally to external stimuli.

Various tests disclosed that neither local anesthesia nor irritation were produced by 84-L.

Isolated Intestine The activity on isolated rabbit ileum is of a low order. Concentrations of 1/100,000 in Tyrode's solution were required to give a perceptible relaxation of normal or spastic strips. The drug produced no effect on the guinea pig intestine.

Isolated Uterus In concentrations of 1/100,000 84-L produced no effect on the isolated uterus from the rabbit or the rat. Virgin guinea pig uteri responded with weak contractions to a 1/100,000 concentration. In lower concentrations the response was barely perceptible or was absent.

The antihistaminic action on the guinea pig ileum was barely detectable and amounted to 1/2,000 to 1/10,000 of the activity of some of the clinically used compounds. Ten guinea pigs were injected intraperitoneally with 50 mg per kilogram of 84-L and thirty minutes later were subjected to a standardized spray of histamine. Nine animals convulsed in three minutes and of these one died. One guinea pig withstood the spray for ten minutes with no signs other than dyspnea. A retest of this guinea pig one and one-half hours after 84-L produced convulsions in seven minutes. All of a group of ten control guinea

Fig. 3—Typical records of respiratory movements in unanesthetized dogs after intravenous injection of 84-J. The signal line marks the duration of the injection. The respiratory movements were relayed by a thread attached halfway between the umbilicus and the end of the sternum.

pigs convulsed in three minutes and three died. From these data we conclude that 84-L does not exaggerate the action of histamine but exerts little protection against it.

Eye Six cats were given the drug in a dosage of 25 mg per kilogram intraperitoneally and three were given 50 mg per kilogram. No evidence of myosis or mydriasis was observed. The local application of a 10 per cent solution produced no change in the pupil.

Blood Sugar In subconvulsant doses 84-L had no effect upon the blood sugar.¹²

Diuretic Action By the Lipschitz assay the diuretic potency is 17.5 times that of urea, or about one half the effectiveness of caffeine.

Analgesia In rats the compound produced evidence of a mild analgesia. The action was less than that produced by aminopyrine.

Respiration Changes in respiration have not been observed except after intravenous doses. In unanesthetized dogs the intravenous injection of 5 mg per kilogram in eight seconds stimulated the rate and depth of respiration for about a minute. Within two to three minutes from the start of the injection the respiration was normal (Fig. 3). When the same dose was injected over a period of sixty seconds, the stimulation was of a lower order and of a shorter duration. The injection of 20 mg per kilogram in eighteen seconds produced an intense stimulation of respiration which lasted about a minute. In three minutes the animal appeared to be normal. In etherized dogs the respiratory changes were much less prominent.

Intravenous doses of 2 to 15 mg per kilogram inhibited the respiration of normal and anesthetized rabbits. In unanesthetized rabbits the rapid injection of 5 mg per kilogram produced an apnea lasting from five to ten seconds. Recovery was complete in three minutes. A dose of 2 mg per kilogram injected in sixty seconds decreased the amplitude and slowed the respiration for thirty seconds. Twenty-five milligrams per kilogram injected in one minute killed one of two rabbits.

In anesthetized dogs lethal doses of 84-L produced death by respiratory failure. These animals could be maintained on artificial respiration long after breathing had ceased.

Circulation In etherized animals the response of the blood pressure to effective doses of 84-L (Fig. 4, Table IV) resembled that produced by epinephrine. The principal difference noticed was a longer duration of the depressor phase. Doses of 0.1 and 0.5 mg per kilogram were ineffective. Some dogs responded feebly to 1 mg per kilogram, but 5 mg per kilogram produced a quick, short-lasting rise in the blood pressure followed by a fall of somewhat longer duration. As the dose was increased the peak of the rise increased until it reached a maximum at about 20 mg per kilogram. The changes in the blood pressure produced by initial doses ranging from 5 to 40 mg per kilogram have been recorded in Table IV.

Fig. 4—The effect of repeated doses of 81 L on the blood pressure of etherized dogs. In each tracing the signal line marks the time for the repetition of the original dose.

*The injection was completed in ten to thirty seconds

†Fall was interrupted by the injection of another compound

‡This rise was preceded by a fall of 8 mm Hg. The duration of the fall was 0.3 minutes

The leg plethysmograph readily demonstrated that the sharp rise in blood pressure produced by intravenous doses of 84-L in dogs was accompanied by an equally sharp decrease in the volume of the leg (Fig 5). However, the vasodepressor phase is poorly reflected.

The close similarity between the response of the blood pressure to 84-L and to epinephrine, coupled with the observation that 84-L exaggerated the action of epinephrine, suggested that it inhibited either the cardiac vagus or those reactions which destroy epinephrine.

The vasodepressor response to stimulation of the right vagus before and after 84-L showed that the intravenous injection of 25 mg per kilogram blocked 25 to 100 per cent of the vagal activity for a period of thirty minutes (Table V). The exaggeration of the pressor response of epinephrine parallels the inhibition of the vagus. Doses of 5 and 10 mg per kilogram of 84-L produced essentially no vagal inhibition (Table V). The mechanism of inhibition is interesting since in doses which completely inhibited the cardiac vagus 84-L had no effect on the vasodepressor response to acetylcholine (Fig 6).

The right vagus was used the blood pressure was recorded from the right carotid artery. All animals except Dog 491 were anesthetized with ether. In Dog 491 the anesthetic was intravenous sodium pentobarbital.

†Complete inhibition for at least two hours.

‡Vagal activity was normal at forty five minutes

Fig 6—The action of 84-L on the response of the blood pressure to acetylcholine epinephrine and faradic stimulation of the right vagus. The doses per kilogram were 84-L 25 mg, acetylcholine 0.4 μ g and epinephrine hydrochloride 2 micrograms.

Repeated injections produced a gradual diminution in the responses of the blood pressure and finally a complete disappearance of all action (Fig 4). These data may provide a key to the explanation of the disappearance of the headache which developed in some patients after a few doses².

Dogs with cords sectioned at approximately the second cervical vertebra and with all superior connections completely removed showed unmistakably that the vasopressor response of 84-L was not dependent upon centers in the brain. After this operation the vasopressor action of 84-L was exaggerated¹⁷ (Fig 7). Rises of blood pressure of 100 to 180 mm Hg were common. Furthermore, the duration of the rise was much longer than in the etherized dogs. After the rise there was no fall unless the compound had been given before the blood pressure reached a stable level.

Electrocardiograms* obtained from etherized dogs which had been injected intravenously with 5 to 50 mg of 84-L per kilogram revealed minimal changes. The heart rate was increased from 150 to 180 beats per minute during the hypertensive phase but returned to the initial rate during the hypotensive phase. Regular sinus rhythm was maintained and such changes in the form of the complex as were noted were those usually associated with rapid heart

*The electrocardiographic studies were made by Dr Maynard B. Chenoweth, Cornell University Medical College.

Fig. 1—The effect of 84 I on the blood pressure before (l) and after (r) section of the cervical cord. Both (A) and (B) sectioned before the control injection (l). The injections in B were made at five minute intervals.

rates Electrocardiograms taken during the terminal stages revealed no changes not typical of anoxia

Cardiovascular responses in unanesthetized dogs In five unanesthetized dogs the rapid intravenous injection (ten seconds) of 5 mg of 84-L per kilogram produced an increase in blood pressure Expressed in millimeters of mercury the elevations were 68, 68, 68, 88, and 118* When the same dose was given in sixty seconds the rise was 31 mm Hg Only two dogs were tested These data indicated that the cardiovascular system of an unanesthetized dog was more sensitive to 84-L than that of the etherized animal Electrocardiograms reflected similar differences Although the rapid intravenous injection of 5 mg per kilogram of 84-L produced insignificant changes in the electrocardiogram of etherized dogs, the same dose in unanesthetized dogs produced a number of changes in the rate and pacemaker location Sinus arrest for periods as long as nine seconds and irregular rapid sinus rhythm interspersed with premature junctional and ventricular contractions were observed Approximately five minutes after the injection the electrocardiogram was normal Doses of 0.1 to 0.5 mg per kilogram produced no changes or only slight changes in the rate and form of the electrocardiogram

FATE OF COMPOUND —

The absence of accumulative effects after multiple doses of 84-L (Tables II and III) suggested that the animals quickly became highly tolerant or that the compound was rapidly destroyed or excreted Although a certain vascular tolerance to the drug developed, no comparable tolerance was seen in any other system

Liver —The role of the liver in the detoxication was examined by subjecting rats first to a series of doses of carbon tetrachloride and then, before hepatic recovery, to multiple doses of 84-L The quantity of 84-L used slightly exceeded that which the rat was able to destroy or excrete so that any limitation in the ability of a key organ to perform its function would be reflected in a greater incidence of reactions in the test group Rats weighing from 180 to 210 grams were given orally 0.166 cc of carbon tetrachloride per 100 grams of body weight This dose was diluted to 0.5 cc with corn oil (Mazola) and given on days 1, 2, 3, 4, 5, 7, and 8 The tests for liver damage and 84-L catabolism were made on the first day after the last dose of carbon tetrachloride The function of the liver was tested by following the duration of the anesthesia produced by sodium pentobarbital, a drug which is destroyed principally in the liver¹³ The results shown in Table VI demonstrate that a dose of 30 mg per kilogram of sodium pentobarbital anesthetized 95 to 100 per cent of the control and the carbon tetrachloride-treated rats Duration of the anesthesia as measured by the righting reflex was one hour in the control group and seven hours in the treated group (Table VI) The administration of 84-L in multiple graduated doses to rats treated similarly with carbon tetrachloride gave little evidence of an exaggeration of the effects seen in normal rats (Table VII) These data suggest that the liver is unimportant in the detoxication of 84-L

*Coagulation of blood interfered with the evaluation of the depressor phase

Kidneys—The administration of multiple doses of 84 L to unilaterally and bilaterally nephrectomized rats demonstrated the importance of the kidney in the elimination of this compound (Tables II and VIII). In sixty rats the left kidney was removed and after four or five days the animals were injected intraperitoneally with repeated doses of 84 L. The schedule of doses was 300 mg per kilogram initially followed on hours 2, 3, 4, 5, 6, 7, and 8 by additional doses of 100 mg per kilogram. Thus, in a period of eight hours the total cumulative dose was 1,000 mg per kilogram. With this schedule the accumulated mortality for the eight hours was 80 per cent in the unilaterally nephrectomized rats and 34 per cent in the normal rats.

There were two groups of bilaterally nephrectomized rats (Table VIII). In one group the total nephrectomy was accomplished six days after the removal of the left kidney. The 84-L was administered twenty-four hours after the last operation. The initial dose was 200 mg per kilogram with subsequent doses of 100 mg per kilogram given on the second, third, fourth, and fifth hours. After an accumulated dose of 400 mg per kilogram 50 per cent of the rats were dead, and after 600 mg per kilogram the mortality was 100 per cent.

*Effect of 84 L on normal rats is summarized in Table II Group I

†Weight range in grams Groups I and II 170 to 200 Group III 204 to 240

In normal rats the LD₅₀ for a single dose was 465 mg per kilogram (Fig 1) and a single dose of 600 mg per kilogram produced a mortality of 75 per cent. When the same schedule of doses was used on a group of rats which had been bilaterally nephrectomized under ether one-half to two hours before the first dose of 84-L, an accumulated dose of 500 mg per kilogram killed eight of fifteen rats and 600 mg per kilogram produced a mortality of 87 per cent. As an additional control on mortality attributable to the operation, the survival of thirteen totally nephrectomized rats was followed. Twenty-four hours after the operation the survival was 85 per cent and after forty eight hours, 54 per cent. Attention should be called to the fact that the residual effects of ether in rats which were dosed on the same day that they were operated provided a significant protection against the lower doses of 84-L.

The value of the kidney in the elimination of 84 L has been shown graphically in Fig 8. Here the mortality in per cent has been plotted on logarithmic probability paper for the cumulative doses administered to normal and to unilaterally and bilaterally nephrectomized rats, and these curves have been compared with the standard intraperitoneal dosage mortality curve (Fig 1). The mortality for the cumulative doses in the normal rats did not change significantly after the first dose. In the unilaterally nephrectomized rats the mortality from the initial dose was higher than in the unoperated animals and con

EFFECT OF NEPHRECTOMY ON INTRAPERITONEAL TOXICITY OF 84 L IN RATS

Fig 8—The schedule for the cumulative dosing of normal and unilaterally nephrectomized rats was: initial dose 300 mg per kilogram at zero time and 100 mg per kilogram at 3, 4, 6, 7 and 8 hours. For the bilaterally nephrectomized rats the schedule was: initial dose 200 mg per kilogram at zero time and 100 mg per kilogram at 3, 4 and 5 hours.

tinued to mount as the doses accumulated. However, the mortality from these accumulated doses did not equal that produced by equivalent single doses. The dosage mortality curve for the accumulated doses in the bilaterally nephrectomized rats paralleled and closely approximated that for the single doses to normal rats.

Excretion—Although the data indicate that the elimination of the compound is accomplished principally by the kidney, the form in which it is excreted has not been determined. No practical chemical test for small quantities of the compound has been devised. However, a bio assay on filaria-infested rats indicated that the equivalent of 63 per cent of a 300 mg per kilogram intraperitoneal dose was excreted during the first twenty-three hours. In spite of the fact that nothing is known about the metabolic fate of 84-L, the low antifilarial activity of its relatives¹⁴ strongly suggests that, in the rat, most of the compound is excreted unchanged.

SUMMARY AND CONCLUSIONS

1-Diethylcarbamy-4-methylpiperazine hydrochloride, also known as Hetazul and 84-L, has a low toxicity and causes few side reactions.

The intraperitoneal LD₅₀ in mice was 248 mg per kilogram and in rats, 465 mg per kilogram. The oral LD₅₀ in mice was 660 mg per kilogram and in rats, 1,380 mg per kilogram.

Mice, rats, rabbits, and dogs readily tolerated intraperitoneal injections of 100 mg per kilogram.

Daily intraperitoneal doses of 50 mg per kilogram in rabbits and 100 mg per kilogram in rats, five days per week for fourteen weeks, produced no evidence of toxicity. Twenty-five milligrams per kilogram twice a day, orally, for two months produced no evidence of toxicity in dogs.

The compound was not irritating, it produced no local anesthesia and had no effect on the eye, on the isolated uterus or intestine, or on the blood sugar. It was mildly diuretic and analgesic. Intravenous doses of 2 to 25 mg per kilogram in unanesthetized dogs stimulated the respiration. The heart and blood pressure were not affected by rapid intravenous injections of 0.5 mg per kilogram, but larger intravenous doses in unanesthetized dogs produced a transient deviation from the normal.

The compound was rapidly excreted by the kidney. In rats and mice the rate per hour was approximately one-third of the intraperitoneal LD₅₀.

LABORATORY METHODS

SCREENING METHOD FOR BLOOD GLUCOSE*

HUGH L C WILKERSON, M D,† AND ERICH HEFTMANN, PH D ‡
BOSTON, MASS

IN THE course of mass surveys carried out by this Section¹ it became increasingly evident that a considerable saving of time and money might be effected through elimination of definitely normal blood samples from routine glucose analysis by means of a simplified test. The method is based on that of Hagedorn and co-workers² but the steps requiring experience in chemical techniques and fluid reagents have been eliminated. The time required for a single analysis is about five minutes, the amount of blood, 0.1 milliliter. This paper describes the screening method and gives the results obtained with the first fifty blood samples.

REAGENTS AND APPARATUS

All reagents are in tablet form. In Boston (and presumably in many other localities) ordinary tap water may be used instead of distilled water.

Tablet 1

ZnSO ₄ , 7H ₂ O-----	10 mg
NaCl-----	190 mg
Talc-----	As binder
Mineral oil-----	As lubricant

Tablet 2

KI-----	100 mg
NaHCO ₃ -----	10 mg

Tablet 3

K ₂ [Fe(CN) ₆], recrystallized-----	128 mg
Na ₂ CO ₃ , anhydrous-----	65 mg
Starch, soluble-----	1 mg
NaCl-----	92 mg

Tablet 4

Tartaric acid-----	80 mg
ZnSO ₄ , 7H ₂ O-----	20 mg
Starch-----	As binder

Heating Tablets

Methenamine ||

The apparatus consists of a Pyrex test tube 16 by 150 mm, graduated at 5 ml, the mouth of which is widened into a funnel, a scoop made of a piece of glass rod, and a portable test tube stand. The stand is so constructed that the

§We gratefully acknowledge the generous help of the staff of Eli Lilly & Company Indianapolis Ind who prepared and furnished reagent tablets

¶Reagent tablets No 1588 Eli Lilly & Company Indianapolis Ind

test tube can be heated in a reproducible manner by the heating tablets, that is the distance between tube and tablets is constant (five eighths of an inch) and drafts are kept out

PROCEDURE

Fill the test tube with water to the 5 ml mark. Obtain 0.1 ml capillary blood from the fingertip or ear lobe by means of a capillary pipette. Deliver and rinse the blood into the water in the tube. Add one Tablet 1 and one Tablet 2 to the tube, put it on the stand, and light two heating tablets underneath it. The blood proteins are coagulated by the zinc hydroxide and form a scum which floats on top of the liquid. As the solution boils, the cake of protein is pushed upward in the test tube by the steam and can be removed with the glass scoop when it reaches the funnel shaped mouth. The funnel prevents the solution from boiling over and unremoved protein from falling back into the tube. When both heating tablets are nearly consumed, light another heating tablet on them and add one Tablet 3 to the test tube. At the end of the second heating period cool the test tube by immersion in cold water and add Tablet 4. When cold, the solution will be either blue, due to the formation of the starch iodine complex, or colorless, if no iodine is present.

RESULTS

The results of the screening method were checked against the blood sugar method of Somogyi³ as modified by Nelson⁵. In order to obtain a more accurate value for the true sugar concentration of the blood, the Somogyi Nelson determination was carried out on a 10 ml sample of venous blood, the 0.1 ml sample for the screening method being taken from the same sample of venous blood. The samples were taken from normal and diabetic subjects.*

Fifty blood samples were subjected to the screening method, then analyzed by the Somogyi Nelson method. Twenty five samples having a true sugar concentration of 170 mg per cent or less by the Somogyi Nelson method, gave a blue color (negative reaction) in the screening method. Four samples had blood sugar values between 170 and 180 mg per cent and gave faint or dark blue colors (negative) or no color (positive) reaction. None of the twenty one blood samples containing more than 180 mg per cent gave a color reaction in the screening test.

DISCUSSION

The amount of potassium ferricyanide in Tablet 3 is so adjusted that it will be completely reduced under the conditions of the test by the glucose present in 0.1 ml blood when the concentration is 180 mg per cent or more. If the glucose concentration in the blood sample is lower than 170 mg per cent, some potassium ferricyanide is left over to oxidize the potassium iodide in Tablet 1 to iodine which produces a blue color with starch upon acidification by Tablet 4. The variability of the results between 170 and 180 mg per cent is due to variation in the tablets, the amount of water, heating, and so forth.

*We wish to thank Dr. A. Marble of the New England Deaconess Hospital for making available the clinical material.

The 180 mg per cent level for capillary glucose has been chosen arbitrarily as the value above which a retest by a conventional blood sugar method seems warranted. Naturally, this level may be adjusted at will by altering the conditions of the test, for example the potassium ferricyanide content of Tablet 3. Inasmuch as a knowledge of the actual blood sugar value is less important in screening diagnostic work than whether or not a certain level is exceeded, the test recommends itself wherever laboratory facilities are unavailable.

SUMMARY

A simple and inexpensive screening method for blood glucose has been described. A blood sample of 0.1 ml may be classified as above or below a certain glucose concentration within five minutes by means of this test. In the first fifty cases examined by this method, twenty-five blood samples below 170 mg per cent glucose gave a negative result, twenty-one samples above 180 mg per cent a positive result, and four samples between 170 and 180 mg per cent both positive and negative results.

AN INCREASE OF COMPLEMENT UNITS BY THE USE OF EGG ALBUMIN

S W BOHLS, M D,* AND PHYLLIS SHAW, B S, M T,† (ASCP)
SAN ANTONIO, TEXAS

THE behavior of complement and amboceptor titrations in complement fixation tests for the serodiagnosis of syphilis has been under study in Santa Rosa Hospital Laboratory for some time. Literature pertaining to the subject is meager.

Periodically difficulty has been encountered, particularly in the complement titration, that was unexplainable from the standpoint of the pH or the reagents used.

Amboceptor titrations resulted in a unit well within the usable range, but the complement titration was unsatisfactory for use, with complete hemolysis in perhaps only the first one or two tubes.

All guinea pigs used for complement had been tested previously for titer and complement fixation and found to be satisfactory. Blood from five guinea pigs was pooled. Since lyophilized complement titrations occasionally exhibited similar reactions, complement per se was eliminated as a possible cause of the difficulty. Inhibition of hemolysis was noted in the complement titrations containing antigen. The pH of the saline was always within usable range.

The absence of albumin in the titration was considered as a possible cause of the difficulty encountered. Varying amounts of pooled negative serum were found to be unsatisfactory as a source of albumin, but the addition to each tube in the titration of 0.2 cc of 50 per cent egg albumin in 0.85 per cent saline as previously recommended by Kolmer for testing spinal fluids, was found satisfactory.

Parallel titrations using the same reagents, except for the absence of the 0.2 cc of 50 per cent egg albumin in 0.85 per cent saline, resulted in the titrations given in Table I.

Supplementary titrations following the eighteen hour incubation of the complement fixation tests rarely result in a change of amboceptor dilution when the units for the test have been determined by a preliminary titration using the 0.2 cc amounts of 50 per cent egg albumin in each tube of the titration. Whereas, the supplementary titrations after the incubation period on tests in which the unit of complement has been determined in preliminary titrations not using the egg albumin, frequently necessitate an increased dilution of amboceptor for tests with a maximum sensitivity.

Variations in the unit of complement with cardiolipin lecithin antigen (a regular antigen have been reported previously¹ and the variation is consistent whether or not egg albumin is used.

CONCLUSION

The use of 0.2 cc of 50 per cent egg albumin in normal saline in each tube of the preliminary amboceptor and complement Kolmer titrations usually results in a higher unit of complement and frequently in an increased dilution of amboceptor to be used in the Kolmer complement fixation test for syphilis. With the addition of the 50 per cent egg albumin, supplementary titrations following the incubation period rarely result in the necessity for a change in the amboceptor dilution to obtain maximum sensitivity.

A COLORIMETRIC METHOD FOR THE DETERMINATION OF MICROQUANTITIES OF ETHANOL IN BLOOD AND OTHER BIOLOGIC FLUIDS

RICHARD J HENRY, M D , CAROL F KIRKWOOD, A.B , SAM BERKMAN, PH D
RILEY D HOUSEWRIGHT, PH D , AND JANE HENRY, PH D
FREDERICK, MD

WITH THE TECHNICAL ASSISTANCE OF RENE F HIRSCH

THE principal methods for the determination of microquantities of ethanol involve its oxidation followed by measurement of the resultant equivalent reduction. Various oxidizing agents have been used^{1, 2} but the majority of methods are based on the work of Widmark⁴ and Nieloux and co workers⁵ and use an acid solution of potassium dichromate. Investigators have varied the procedure of distilling the alcohol into the acid dichromate and both titrimetric^{6, 8} and colorimetric^{9, 11} methods have been used to determine the reduced dichromate. The maximal sensitivity of these methods is approximately 20 μ g of ethanol. These methods are not specific, since any volatile substance oxidizable by dichromate will be determined as ethanol. The presence of such substances as methanol, formaldehyde, acetone, and other aldehydes and ketones gives high results.^{10, 11} The accuracy of these methods in the determination of ethanol is open to question unless such substances can be removed or are known not to be present in quantities causing interference. This is especially important in the determination of the ethanol level in blood for medicolegal purposes.

A new method for the determination of ethanol has been devised involving the conversion of ethanol to acetaldehyde and the determination of the latter colorimetrically with p hydroxydiphenyl.^{14, 15} This method is considerably more sensitive and more specific than pre existing methods. Furthermore it retains the advantages of requiring no special apparatus and of being simple to carry out.

PROCEDURE

Up to 20 cc of the sample to be analyzed are placed with several glass beads in a 50 cc single side arm distillation flask connected with a small Liebig condenser. Distilled water is added to 20 cc, followed by 0.1 cc 10 per cent NaOH. The flask is closed tightly with a rubber stopper and at least 5 cc distilled. The entire distillate is then washed into the flask of an identical setup the flask in this case containing 25 cc saturated aqueous K₂Cr₂O₇ (CP), 0.5 cc concentrated H₂SO₄ (CP), and several glass beads (Care must be taken to prevent any of the dichromate from entering the side arm since dichromate interferes with the color reaction). The flask is stoppered immediately with a rubber stopper and the acetaldehyde formed is distilled into a graduated receptacle such as a centrifuge tube, in an ice bath.* The volume that must be distilled to obtain all the

From Camp Detrick

Received for publication Nov 3 1947

What percentage of the ethanol was oxidized to acetic acid was not determined. Consistency of the results obtained indicates that the fraction of the ethanol completely oxidized remained constant under the conditions of the procedure outlined. Distillation from the dichromate sulfuric acid mixture was begun immediately after addition of the ethanol and no differences in results were observed whether this mixture was hot or cold at the time of addition of the ethanol. As soon as one sample has been distilled another can be added to the reaction mixture. Thus several samples can be distilled in succession without changing the dichromate sulfuric acid mixture.

acetaldehyde formed varies directly with the amount of ethanol present in the original sample. It was found that if the original sample contains 20 μg of ethanol at least 5 c c must be distilled, for 10 μg of ethanol a distillation of 2 c c suffices.

The acetaldehyde in the distillate is then determined colorimetrically by reaction with p hydroxydiphenyl^{14, 15}. One cubic centimeter of the distillate is placed in an 18 by 150 mm Pyrex test tube. One drop of 5 per cent CuSO_4 is added, followed by 6.00 c c of concentrated H_2SO_4 (special, As and N free) added slowly, with shaking, in an ice bath. One tenth cubic centimeter of 1.5 per cent p hydroxydiphenyl in 0.5 per cent NaOH is added directly to the solution and dispersed by vigorous shaking. The tube is placed in a 30° C water bath and after approximately fifteen minutes the reagent is redispersed by shaking. After incubation for at least thirty minutes the tube is placed in a boiling water bath for ninety seconds to dissolve excess reagent. The tube is then placed immediately in an ice bath and brought to room temperature. The color (deep violet) is read in a photoelectric colorimeter against a sulfuric acid reagent blank which has been treated as described (except that 100 c c of water is used instead of the distillate). A filter having peak transmittance at approximately 560 $\text{m}\mu$ is used. The color can be read immediately and is stable for several hours.

Fig 1—Color intensity obtained with known quantities of ethanol

In our experiments the Klett Summerson photoelectric colorimeter was used with a Klett No 54 filter. Fig 1 presents graphically the results of distilling 2 and 5 c c quantities in the second distillations, using known concentrations of ethanol. The solid portions of the curves were drawn from the experimental points (20 for curve A, 32 for curve B) by the method of least squares. It is apparent from the graph that the maximal amounts of ethanol falling on the straight line (solid) portions of the curves for the 2 and 5 c c distillations are approximately 10 and 20 μg , respectively. Several experimental points above these limits are plotted in Fig 1 to show the variability of results obtained at higher concentrations.

Sensitivity and Precision—The sensitivities for the 5 and 2 c c distillations are approximately 1 and 0.5 μg of ethanol, respectively. It was found that the sensitivity could be increased to approximately 0.2 μg by distilling only 1.20 c c in the second distillation. Thus, if a 10 c c sample is available a concn

tration of 0.02 μg per cubic centimeter can be determined. The standard error of a single determination in the range between 5 and 20 μg of ethanol for the 5 c.c. distillation is 5 per cent and between 2 and 10 μg of ethanol for the 2 c.c. distillation, 7 per cent. Since nineteen times out of twenty a single determination will be within ± 2 standard errors of the true value, the error of a single determination is ± 10 per cent for the 5 c.c. distillation and ± 14 per cent for the 2 c.c. distillation* (The experimental error is greater at or near the limit of sensitivity).

The error, of course, can be reduced by running replicates. The number of replicates required (N) to give a desired precision (P) can be computed by substitution in the following formulas:

$$N = \frac{100}{(P)^2} \quad (\text{for 5 c.c. second distillation})$$

$$N = \frac{196}{(P)^2} \quad (\text{for 2 c.c. second distillation})$$

Interfering Substances—The following substances did not give color in 100 μg amounts, distilling 2 c.c. in the second distillation: dihydroxyacetone, fructose, d-xylose, d-ribose, succinic acid, fumaric acid, citric acid, malic acid, isaconitic acid, α -ketoglutaric acid, acetone, ascorbic acid, tartaric acid, urea, glycine, tryptophane, methionine, methanol, glucose, pyruvic acid, glycerol, acetic acid, and lactic acid (up to 500 μg).

In Table I are listed those substances which were found to give color, distilling 2 c.c. on the second distillation. One hundred microgram amounts were used and the interference is given in terms of micrograms of ethanol giving an equivalent intensity of color. Obviously, acetaldehyde itself would give the color reaction.

TABLE I SUBSTANCES INTERFERING IN THE DETERMINATION OF ETHANOL

INTERFERING SUBSTANCE	COLOR YIELDED BY 100 μO IN TERMS OF μO ETHANOL
Oxalacetic acid	3
α -Glycerophosphate	20
Glyceraldehyde	1
n-Propyl alcohol	22 (blue color)
n-Butyl alcohol	20 (purple color)
Isobutyl alcohol	2
Allyl alcohol	10 (red color)
n-Amyl alcohol	6
Isoamyl alcohol	6

In many instances the first distillation procedure could be omitted. It was found, however, that lactic acid interfered and that this interference was quite variable. After several attempts, the only procedure found effective in eliminating lactic acid interference was the preliminary distillation from basic solution.

A good portion of this error undoubtedly is dependent on the accuracy with which the second distillate is measured (the second distillates were collected and the volume measured in graduated centrifuge tubes) and on the variation in the Klett colorimeter tubes used (standardized to ± 3 Klett scale readings).

Determination of Ethanol in Blood—The blood level of ethanol important from the medicolegal aspect centers around 2 mg per cubic centimeter. Ethanol was added to a concentration of 1.00 mg per cubic centimeter to samples of whole citrated blood from ten individuals. One-tenth cubic centimeter of the blood-alcohol mixture was diluted to 5.00 cubic centimeters. Four and one-half cubic centimeters of N/12 H_2SO_4 and 0.50 cc of 10 per cent $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$ were added, making a total volume of 10.00 cubic centimeters. The ethanol in 1.00 cc of the supernatant was determined by the procedure described. To eliminate error arising from variation in the colorimeter tubes, a single tube was used in the blood determinations for all colorimeter readings. Blood samples analyzed after standing overnight gave the same results as those analyzed immediately after the addition of ethanol. The average recovery for forty-two determinations on these samples was 98.6 per cent. The standard error of a single determination was ± 3 per cent, indicating that nineteen times out of twenty the value obtained from a single determination will be within ± 6 per cent of the true value.

Without preliminary precipitation of blood proteins and erythrocytes with tungstic acid, very high blank readings were obtained, presumably due partially or totally to acetaldehyde in the erythrocytes.¹⁶ Similarly, high blanks were obtained if the first distillation was omitted.

Values for the normal ethanol content of blood reported in the literature range from 4 to 40 μg per cubic centimeter^{1, 3, 17} and those for interfering substances estimated as ethanol have been reported as 40 μg per cubic centimeter.¹⁸ In our experiments blank determinations (without added ethanol) on blood samples from thirteen normal individuals gave values from 1 to 10 μg per cubic centimeter, with an average of 6 μg per cubic centimeter. There is no assurance that these values represent the true normal ethanol level since this method of determination is not absolutely specific. Such levels obviously do not interfere in the determination of ethanol concentrations in blood important from a medicolegal aspect.

The extreme sensitivity of this method makes it possible to do blood alcohols on the amount of blood obtainable from finger puncture. The collection and initial dilution of the blood could be carried out with a white blood cell dilution pipette (giving a dilution of 1:20). Before this could be accepted from a medicolegal aspect it would be necessary to ascertain whether the blood alcohol level is the same in blood obtained by finger puncture as in the blood obtained by venipuncture.

It is noteworthy that methanol and acetone do not interfere in this test.

SUMMARY

A method for the determination of ethanol in blood and other biologic fluids is described based on oxidation of the alcohol to acetaldehyde with subsequent determination of the latter photocolometrically with p-hydroxydiphenyl reagent. This method is more sensitive than pre-existing methods and has a precision of approximately ± 6 per cent on a single blood determination.

THE MICROCOLORIMETRIC DETERMINATION OF SODIUM IN HUMAN BIOLOGIC FLUIDS

ANTHONY A. ALBANESE, PH.D., AND MARILYN LEIN
NEW YORK, N. Y.

BARBER and Kolthoff¹ in 1928 described the use of the triple salt, uranyl zinc sodium acetate, for the gravimetric determination of sodium. Subsequently Butler and Tuthill² applied this method with modifications to the determination of sodium in biologic products. Although the gravimetric procedure gives good results, its operation is tedious and requires large amounts of often scarce biologic material. More recently one or both of these shortcomings have been overcome in part by treatment of the precipitate by various colorimetric³ or titrimetric⁴ reactions. In using these more rapid but also more complex techniques, we gained the impression that greater ease of operation would be achieved if the microquantities of sodium contained in 0.2 cc of serum or plasma could be measured in terms of the yellow color of the triple salt complex. Examination of the literature showed that in 1929 Caley and Foulk⁵ had applied this principle to inorganic samples with limited success. Apparently the large amounts of material requisite for the procedure and the difficulties embodied in measuring the density of the resultant yellow color by the then used optical colorimeters discouraged the further application of this ideally simple procedure to inorganic materials⁶ and biologic specimens. The excellent results which we obtained in preliminary tests of this principle in which the Klett-Summerson photoelectric colorimeter was employed for measuring the density of the yellow color of solutions containing varying amounts of the sodium zinc uranyl acetate complex prompted us to attempt the adaptation of this technique to the determination of sodium in biologic fluids. The analytic adequacy of the method which was evolved as the result of this effort was amply shown by recovery and reproducibility tests. The concordant results obtained with this rapid technique when employing 0.2 cc samples of urine, cerebrospinal fluid, and various blood fractions recommends its use for pediatric studies.

EXPERIMENTAL

Reagents —

Uranyl zinc acetate⁷ 10 Gm of uranyl acetate were dissolved in 50 cc of boiling water containing 2 cc of glacial acetic acid. In another flask 30 Gm of zinc acetate were dissolved in 50 cc of boiling water containing 1 cc of glacial acetic acid. The boiling solutions were mixed and again heated just to boiling. After standing overnight at room temperature, the resultant solution was filtered by gravity and mixed with an equal volume of 95 per cent ethanol.

From the Department of Pediatrics, New York University College of Medicine and the Children's Medical Service, Bellevue Hospital.
Received for publication Nov. 7, 1947.

This solution was refrigerated at 4° C for forty eight hours and then filtered by gravity for use. The reagent is stable at room temperature.

Ethanol 95 per cent by volume

Trichloroacetic acid 20 per cent solution

Sodium standard 508.4 mg of oven dried (100° C) sodium chloride were dissolved in 100 c.c. of triple distilled water, 1 c.c. of this solution is equivalent to 2 mg. of sodium.

DETAILS OF PROCEDURE

In order to determine the colorimeter filter best suited for the photoelectric measurement of the yellow color of sodium uranyl zinc acetate the spectral transmission of solutions of the salt equivalent to 1 mg. of sodium was measured in a Coleman Universal spectrophotometer, Model 11. These data indicated that

Fig. 1—Relation of color intensity to amount of sodium. Each point represents the average of five determinations. The bars above and below each point indicate the deviation range of the readings.

maximum optical density for this colored solution occurs in the region 420 to 440 μ and that to realize maximum sensitivity for the test the readings should be made with filter S-42.

The analytical efficacy of the scheme was ascertained as follows. Suitable aliquots (0.1 to 0.4 c.c.) of the standard in 15 c.c. graduated centrifuge tubes were each treated with 1 c.c. of the reagent. After refrigeration for one hour at 4° C the samples were centrifuged and the supernatant fluid decanted and discarded. The yellow precipitate was washed by centrifugation with 2 c.c. of 95 per cent ethanol and dissolved in 5 c.c. of water. These solutions were transferred to the colorimeter tubes and then density measured in the Klett

Summerson photoelectric colorimeter using filter S-42. The results of this experiment, which are shown in Fig 1, demonstrate that the color intensity of the solution varies in accordance with Beer's law for this range of sodium concentration. This color was found to be stable for several hours.

The deviations of the color readings from the mean indicate that the experimental error of the method is approximately ± 5 per cent, which is no greater, if not less, than that incurred in the gravimetric, titimetric, or other colorimetric methods.

The adequacy of the one hour of refrigeration and the single alcohol washing employed in these tests was demonstrated by the concordance of the readings of samples of the standard so obtained with those of similar samples which were allowed to stand in the refrigerator overnight and which were washed three times with 95 per cent ethanol.

Since the application of the method to urine was expected to entail the removal of phosphate ions, solutions of KH_2PO_4 which contained the interfering ions in more than twice then normal concentration in the urine were treated in the manner described for the sodium standard. This test disclosed that the precipitate obtained under these conditions, unlike the sodium acetate complex, was insoluble in water, could be removed by centrifugation, and did not contribute any measurable color to the supernatant fluid. This observation indicated that the urinary phosphates could be readily disposed of in this manner rather than by the use of supplementary reagents.² The analytical adequacy of removing phosphate ions by this scheme was further shown by the agreement of sodium values of 0.2 and 0.3 cc aliquots of the standard before and after the addition of 2 mg of KH_2PO_4 (Table I). This amount of phosphate ion is equivalent to approximately 5 Gm of this ion per liter or about twice its normal concentration in human urine.

APPLICATION OF METHOD TO BIOLOGIC MATERIALS

In applying the technique to urine derived from adults and children the following procedure was found satisfactory: to 0.2 cc of urine in a 15 cc centrifuge tube was added, with mixing, 1 cc of reagent. After refrigeration for one hour at 4°C the mixture was centrifuged at 3,000 revolutions per minute for ten minutes. The supernatant fluid was discarded and the tubes were carefully drained by inversion. The yellow precipitate was resuspended in 2 cc of 95 per cent alcohol, washed by centrifugation, and again drained by inversion. The precipitate was dissolved in 5 cc of distilled water. (The turbidity which may result from the presence of an excess of phosphate ions is easily removed by centrifugation.) The clear yellow supernatant fluid was decanted into the colorimeter tubes and the intensity of the yellow color measured in the Klett-Summerson colorimeter using an S-42 filter. A parallel determination was also done on a 0.2 cc aliquot of the standard. The sodium content per cubic centimeter of urine was obtained from the following formula:

$$\text{Reading of unknown} / \text{reading of standard} \times 0.4 \text{ mg of Na} \times 5$$

It is obvious that careless handling of the tubes during the washing processes will result in the loss of precipitate which will lead to serious analytic errors. For this reason all determinations should be done in duplicate.

The sodium content of spinal fluid also can be determined directly in 0.2 cc samples as described for urine. The presence of the small amounts of phosphate ions and protein which usually occur in this material does not interfere with this assay.

TABLE I RECOVERY OF ADDED SODIUM

SAMPLE	SODIUM ADDED (MG)	SODIUM FOUND (MG)	RECOVERY OF ADDED SODIUM (%)
KH ₂ PO ₄ , 2 mg	0	0	
KH ₂ PO ₄ , 2 mg	0.4	0.4	100
KH ₂ PO ₄ , 2 mg	0.6	0.6	100
Urine P, 0.2 cc	0	0.129	
Urine P, 0.2 cc	0.2	0.327	99
Urine G, 0.2 cc	0	0.557	
Urine G, 0.2 cc	0.2	0.748	95.4
Urine M, 0.2 cc	0	0.473	
Urine M, 0.2 cc	0.2	0.668	97.5
Serum D, 0.1 cc	0	0.315	
Serum D, 0.1 cc	0.2	0.520	102
Serum W, 0.1 cc	0	0.308	
Serum W, 0.1 cc	0.2	0.515	103
Plasma C, 0.1 cc	0	0.362	
Plasma C, 0.1 cc	0.2	0.562	100

In the analysis of serums, plasmas, or whole blood 0.2 cc aliquots are treated with 0.6 cc of 20 per cent trichloroacetic acid and, after centrifugation 0.4 cc of the supernatant fluid (equivalent to 0.1 cc of the original sample) is treated with 1 cc of the reagent and the determination completed as described for urine. In practice whenever sufficient material is available it is more convenient for duplicate analyses to obtain two 0.4 cc aliquots from 0.5

TABLE II SODIUM CONTENT OF VARIOUS HUMAN BIOLOGIC FLUIDS

SUBJECT	SAMPLE	SODIUM CONTENT
C, Adult, male	Serum	316 mg %
E, Adult, female	Plasma	307 mg %
H, Adult, male	Whole blood	224 mg %
J, Infant, female	Serum	325 mg %
W, Infant, male	Cerebrospinal fluid	285 mg %
D, Infant, female	Cerebrospinal fluid	312 mg %
V, Infant, female	Cerebrospinal fluid	294 mg %
J, Premature infant, male	Urine	129 Gm /day
G, Infant, male	Urine	314 Gm /day
S, Infant, male	Urine	550 Gm /day
A, Adult, male	Urine	375 Gm /day
M, Adult, female	Urine	37 Gm /day

cc portions of the blood fractions to which are added 1.5 cc of the trichloroacetic acid solution. The adequacy of the technique as applied to these biologic fluids is indicated by the quantitative recovery of added sodium (Table I).

The results of analyses of biologic fluids obtained from human subjects of various ages are given in Table II. It will be noted that these are in the range of the values reported by others.

SUMMARY

A rapid microcolorimetric procedure for the estimation of the sodium content of biologic fluids has been described which yields values comparable to those of methods requiring larger amounts of material and greater expenditure of time

A NEW COLORIMETRIC METHOD FOR THE DETERMINATION OF PREGNANDIOL

JOSEPH W. COLDZIEHER M.D.*

NEW YORK, N. Y.

THE earliest methods for the quantitative determination of pregnandiol were gravimetric. Some years later Talbot and co-workers¹ described a colorimetric technique. The addition of sulfuric acid to pregnandiol produced a color with a maximum absorption at 420 millimicrons. The accuracy of the method was reported to be within 3 per cent for quantities of pregnandiol between 0.05 and 0.3 milligrams. The relationship between color density and quantity of pregnandiol was according to the equation $C = 2 - \frac{\log C}{K}$. Although this reaction was entirely satisfactory in the hands of Talbot and co-workers¹ others^{2,3} found that it shared some of the well known unpleasant habits of sulfuric acid colors in general. The Liebermann-Burchardt reaction for instance, has a tendency to develop adventitious tints which may be most disturbing. Other colorimetric methods using sulfuric acid often have been replaced for the same reason. Guterman³ found spurious colors so troublesome during his pregnandiol determinations that it became necessary for him to modify his technique considerably and to prepare fresh reagents every two to three days.

In view of these facts an attempt was made to develop another color reaction which would be at least as sensitive as the sulfuric acid method yet which would not develop adventitious colors. Of a number of reactions tested one in particular gave indications of being suitable. It has been reported⁴ that cholesterol produces a characteristic color when added to acetyl chloride and zinc chloride in a solution of glacial acetic acid. Subsequent workers⁵ developed this reaction into a quantitative method for the determination of blood cholesterol. In our experience it has distinct advantages over the usual Bloor method. Despite certain theoretic predictions it was found that pregnandiol gives a stable quantitative color reaction with acetyl chloride and zinc chloride within certain limits the quantity of pregnandiol and the color intensity have a straight line relationship so that direct colorimetric readings can be made.

EXPERIMENTAL

Carefully recrystallized pregnandiol was used throughout. Ether alcohol solutions containing 0.10 and 1.0 mg. per milliliter were prepared. The desired quantity was pipetted into the reaction vessel and the solvent evaporated. The

Part of the expense of this study was defrayed by a grant from Averett McKenna & Harrell, Inc., Ltd., New York, N. Y., to Dr. E. C. Hamblen. The pregnandiol was supplied from this source.

Received for publication Nov. 11, 1941.

St. Clare's Hospital.

zinc chloride reagent was prepared by dissolving 38 Gm of pure zinc chloride in sufficient glacial acetic acid to make a final volume of 100 milliliters

The absorption spectrum of the color complex, after development for thirty minutes at 50°C , is shown in Fig 1. Maximum absorption occurred between 370 and 450 millimicrons. At wave lengths below $300\text{ m}\mu$ the solvent became too opaque for further determinations.

Various factors which might affect the color development, such as proportion of reagents, temperature, time, and concentration, were studied.

Fig 1

Fig 2

It was found that 25 cc of acetyl chloride were most suitable to a final volume of 10 cc attained by the addition of zinc chloride reagent.

The highest temperature at which color development could be carried out without substantial losses of acetyl chloride by volatilization was found to be 50°C .

Color development at a constant temperature of $50 \pm 2^{\circ}\text{C}$ proceeds rapidly during the first fifty minutes. Small quantities of pregnandiol (less than 0.2 mg) attain a constant color density by 150 minutes, but with larger amounts (0.3 to 1.0 mg) the color continues to increase in density even after 300 minutes of incubation. When cooled to room temperature the color is stable and remains constant for at least two and one-half hours.

A different aspect of the relationship between color density, concentration and incubation time is shown in Fig 2. The data are taken from runs carried out in triplicate. It will be seen that color versus concentration is a straight line relationship if the heating time is thirty to fifty minutes, incubation for longer than sixty minutes yields aberrant results with higher concentrations of pregnandiol.

It was found impracticable to control the temperature and the heating so closely that the use of a standard solution became unnecessary. With the use of a standard (0.5 mg pregnandiol) the method was found to be accurate within 4 per cent.

PROCEDURE

The unknown quantity of pregnandiol is dissolved in a suitable amount of solvent, such as ether alcohol, and an aliquot representing approximately 0.1 to 1.0 mg is pipetted into a 10 cc glass stoppered volumetric flask. The solvent is evaporated off. Approximately 6 cc of zinc chloride reagent are placed in the flask and 2.5 cc of acetyl chloride are added from a small burette. A standard for comparison, representing 0.50 mg of pregnandiol, is prepared in similar fashion. The flasks are incubated in a hot water bath at 50° C for thirty minutes. The flasks are then dipped briefly in ice water until cool and are allowed to stand at room temperature for twenty minutes. The volume is adjusted to 10 cc with zinc chloride reagent. After careful mixing of the solution to insure color uniformity, it is ready for reading.

SUMMARY

A new colorimetric reaction with pregnandiol, based on its interaction with acetyl chloride and zinc chloride in glacial acetic acid solution is described. The characteristics of the reaction and the technical procedure are discussed briefly.

We express our thanks to Dr. W. J. Dann of the Department of Biochemistry for the spectrophotometric determinations.

THE EFFECT OF CHLORINE ON COMPLEMENT FIXATION

ANNE C KIMBALL, PH D, AND PAUL W KABLER, PH D, MD
MINNEAPOLIS, MINN

MANY laboratories are equipped with continuous-flow water stills which permit considerable quantities of chlorine in the tap water to be condensed in the distillate. In our experience with a Bainstad "Q" type of still, the chlorine content of the distillate may be as high as the water from which it is prepared, and may, therefore, fluctuate in relation to the chlorine residual of the undistilled water.

When this still was first put into use the distillate was used in preparing saline for the Kolmer-Wassermann test and we were not able to get a complement titration in the approved dilution range even though all the biologic reagents had been satisfactory when titrated with saline of distillates from other stills. This quality of interfering with the complement titrations was found to correlate with the chlorine residual of the various distillates.

Directions for making the saline for Kolmer's modification of the Wassermann test specify the use of 0.85 per cent sodium chloride. The addition of 10 cc of 10 per cent magnesium sulfate to each liter is recommended but is not always essential. Heating in an Arnold sterilizer for one hour is considered advisable if the saline is not used immediately.^{1, 2} No specific criteria of acceptable water are given in reference to chlorine residual.

High Chlorine Residual (Above 0.8 Parts Per Million)—When the chlorine residual of the water is 0.8 parts per million or higher, complete hemolysis is not obtained in any tubes of the hemolytic titration using Kolmer's method. Sheep cell suspensions using saline with these high chlorine residuals show a slight change in color, appearing darker and somewhat brown. At times even lower chlorine residuals will prevent complete hemolysis in all of the titration tubes.

Study of Lower Chlorine Residuals (0.6 Parts Per Million or Less)—The total chlorine residual of freshly distilled water was determined with a comparator using the orthotoluidine method.³ Chlorine free water (Table I, A) was obtained by autoclaving a portion of the water for twenty minutes at 15 pounds, once or twice as needed. Water containing three intermediate amounts of chlorine (B, C, and D) was prepared by mixing the chlorine-free (A) and the chlorine containing (E) water.

Five 0.85 per cent saline solutions with magnesium sulfate added as recommended by Kolmer, were prepared using distilled water A, B, C, D, and E (as in the preceding paragraph). All reagents for use in the Kolmer-Wassermann test were prepared with the five saline solutions and five titrations and quantitative tests were set up. In the first set of experiments five portions of

From the Minnesota Department of Health, Section of Medical Laboratories.
Received for publication Nov. 17, 1947.

sheep cells were washed and packed separately with the five saline solutions of varying chlorine residuals. For the second set of experiments the sheep cells were washed, packed, and diluted to 20 per cent with chlorine free saline, and five portions were further diluted to 2 per cent with the varying salines. The same Kolmer antigen and hemolysin were used in both experiments, while the Lyovac complement and positive sera were different.

The results of the ten titrations and quantitative tests are shown in Table I. It is to be noted that with each increase in chlorine residual more hemolysin or more complement or more of both is required for the tests as indicated by the titration.

TABLE I

EXPERIMENT	SOLUTION	CHLORINE RESIDUAL (P.P.M.)	HEMOLYSIN TITRATION	ACTIVE UNIT OF COMPLEMENT IN ML. OF 1:30 DILUTION	QUANTITATIVE KOLMER WASSEEMANN (MI. OF POSITIVE SERUM)					
					0.2	0.1	0.05	0.025	0.0125	CONTROL 0.2

	B	12	16000	0.5	4	4	5(1)	-	-	-
	C	25	15000	0.4	4	4	3(1)	-	-	-
	D	37	14000	0.5	4	3(1)	1(-)	-	-	-
	E	5	14000	0.5	4	5(1)	-	-	-	-

*Readings made ten minutes after clearing of controls

Reading made after one hour of incubation is shown in parenthesis if different from the earlier reading

Quantitative tests were set up using four different positive sera on each day. The results with only one sera are shown in Table I. The results were similar with all sera, that is slightly weaker reactions with the chlorine containing saline.

DISCUSSION

These results indicate that saline made with chlorine free distilled water should be used for diluting reagents for complement fixation tests. The advantages are as follows:

1. Removal of one factor which may make it impossible to get a titration in the approved range.
2. Higher sensitivity of tests.
3. Lower cost of reagents: this is particularly important in reference to the complement.

It is interesting to note that the actual tests do not indicate that the chlorine has an enhanced deleterious effect on the complement during the long incubation fixation. The explanation of this is not apparent from the present observations. This study included only the Kolmer Wassermann complement

fixation test, but it seems reasonable to assume that the same effect would be seen with any complement fixation procedure

Distilled water containing chlorine may be rendered chlorine-free by several methods

- 1 Storage for one to several months
- 2 Boiling to two-thirds or one-half the original volume
- 3 Autoclaving at fifteen pounds pressure for twenty minutes once or twice as needed
- 4 Inserting an activated-carbon filter to remove the chlorine from water going to the still

Before use, the water must be tested for chlorine residual. Since a satisfactory water must be chlorine-free, there is no need to determine the content if present.

CONCLUSIONS

1 Attempts to titrate the reagents for the complement fixation test are unsuccessful when distilled water with a high chlorine residual (0.8 parts per million or higher) is used in preparing the saline solution.

2 Complement fixation tests using water with lower chlorine residuals (0.6 parts per million or less) require more hemolysin or more complement or more of both than tests using chlorine-free water.

3 Only chlorine-free water should be used in saline for complement fixation procedures.

THE DYNAMICS OF PROTEIN METABOLISM

I THE INTERRELATIONSHIP BETWEEN PROTEIN AND CALORIC INTAKES AND THEIR INFLUENCE UPON THE UTILIZATION OF INGESTED PROTEIN FOR TISSUE SYNTHESIS BY THE ADULT PROTEIN DEPLETED RAT

EARL P BENDITT, M D, ELEANOR M HUMPHREYS M D, ROBERT W WISSIER

INTRODUCTION

OPTIMAL nutrition remains a major problem of medicine and surgery despite the accumulating knowledge concerning vitamins amino acids and other essential dietary factors. Until certain relationships are more clearly elucidated however, we still cannot utilize this knowledge with full effectiveness. Important among these is the interrelationship between the level of protein intake, the energy intake, and the utilization of dietary protein. The present studies were undertaken in order to examine this interrelationship under controlled conditions. The basic plan was to study the rate of utilization of protein for tissue fabrication by the protein depleted animal under the following circumstances: (1) varying caloric intake with constant protein intake, (2) varying protein intake with constant caloric intake, and (3) simultaneous variation of caloric and protein intakes.

In these studies we have examined not only gross rates of fabrication of protein in the body as a whole but also rates in various body compartments. This paper deals only with the gross metabolism of protein in the rat. A second paper will contain evidence which demonstrates a fundamental similarity of the protein fabricating mechanisms of the rat and man. Later papers will deal with the relative rates of protein synthesis in various body compartments of protein depleted animals.

MATERIALS AND METHODS

In these experiments protein depleted, young adult male albino rats (Sprague Dawley) were used. At the start of the depletion period their weights averaged 210 grams. For two and one-half months they were depleted upon a low protein diet which contained adequate offerings of calories, vitamins, minerals, and other dietary essentials. The depletion diets and regime have been described.¹ At the end of the depletion period the average weight of the animals was 154 grams. Animals were then individualized. Groups of five or six animals

were selected to be fed each of the experimental diets. The animals were chosen so that each group was comparable with respect to initial weight, weight loss, serum protein concentration, and hemoglobin concentration.

The basic composition of the diets was the same in all three experiments. For the protein, a half and half mixture of bovine lactalbumin* and casein vitamin test was used. The composition of the diets is given in Tables I and II. It is evident from Table I that in Experiment 1 the absolute quantity of protein offered per day was constant, but the quantity of carbohydrate varied. In Experiment 2 the absolute quantity of protein fed per day was varied and the total calorie value of the diet offered was maintained constant. Experiment 3 utilized the same diet throughout, offered in different amounts to different groups of animals. Diets were offered in weighed amounts each day. Diet consumption was measured daily and the experimental feeding period was fourteen days.

TABLE I COMPOSITION OF DIETS

Initial determinations of the various blood compartments were made by methods which have been described in detail elsewhere.² At the end of the test period these values were re-determined. The animals were then sacrificed. Liver, heart, kidneys, and approximately 40 per cent of the blood were removed. The gastrointestinal tract was stripped of its content. The carcass with the residual contents, including the gastrointestinal tract, was weighed and analyzed for water, fat, protein, and ash.

*Borden's No. 1542

†SMACO Vitamin test, General Biochemicals Inc.

TABLE II DAILY VITAMIN RATION

VITAMIN	QUANTITY OFFERED PER DAY
Thiamin chloride	50 gamma
Riboflavin	120 gamma
Niacin	200 gamma
Pyridoxine HCl	90 gamma
Calcium pantothenate	190 gamma
Choline chloride	27 mg
Oleum percomorphum	
Vitamin A	60 USP units
Vitamin D	9 USP units

All diets offered the equivalent of the vitamins per animal per day except in Experiment 3. In this experiment the vitamin offering was proportional to the quantity of diet offered diet 3 D providing the standard allowance Diet 3 F otherwise identical with 3 A offered the standard quantities of the vitamins

The method of carcass analysis was as follows Each carcass was cut into pieces with a scissors and the pieces ground in a motor driven meat grinder Grinder and parts were rinsed with alcohol and wiped with a weighed filter paper Crinding washing and paper were collected in a weighed evaporating dish and dried at a temperature of 60 C in a hot air oven for a minimum of five days Following this the dish and contents were weighed and the contents were transferred to a weighed fat free aluminum dish and extracted for twelve hours with alcohol in a Soxhlet extractor They were reextracted for twelve hours with ether Following this, the dish and contents were dried again for forty eight hours in the 60 C oven cooled in a desiccator and weighed Preliminary to a lung the dried fat free carcass was ground to a fine powder in a motor driven pulverizer Dry 2 Gm samples were heated in a muffle furnace at 600 C for six hours cooled in a desiccator and weighed

It was found in early experiments that complete recovery of the lost weight by these protein depleted adult animals was not associated with significant changes in the ash content of the carcass and that differences of the order of magnitude found were within the limits of variation among individual animals Therefore in Experiments 2 and 3 the ash content was determined on single samples from each of the diet groups and the pooled average so obtained was used to compute the protein content of each carcass

Protein was computed by deducting the weight of the ash from that of the dry fat free carcass In order to ascertain how closely this value approximated the conventional $N \times 6.25$ value for the estimation of the protein the following experiment was performed Nitrogen determinations were made on seven carcasses of animals of widely differing weights The nitrogen concentration of the ash free carcass was found to be 15.7 ± 0.05 per cent This value is in reasonable agreement with the commonly accepted value for animal proteins of 16.0 per cent nitrogen and with the value of 15.4 per cent found by Addis and co workers³

The livers were analyzed for fat water protein and water soluble constituents by a method similar to that used for the carcasses The details will be given in a later paper All hearts and kidneys were weighed and selected ones were analyzed

OBSERVATIONS

Table III presents the observations on body weight diet consumption carcass fat and protein Recorded in Table IV are the average of the mean weights of the animals for the fourteen day experimental period the average weight gains the calculated surface areas, the average daily protein intakes caloric intakes and rates of protein gain

The protein intakes are recorded as grams of protein ingested ($N \times 6.25$) per kilogram of body weight per day The rate of protein utilization is recorded in an analogous fashion as grams of protein gained per kilogram of body weight per day Caloric intake appears as calories per square meter of body surface per day These units may appear unnecessarily devious and cumbersome

some, an inspection of the nature of the quantities, however, shows that they reduce the measured values to a system of units which is independent of the size of the animal. The advantages of this for comparing animals of different sizes within the same species or of different species are obvious and will become clearer.

*The values given are means and standard errors for animals fed each diet. Standard errors computed by $SE = \sqrt{\frac{\sum (x-m)^2}{n(n-1)}}$

Protein gains were measured from an initial value for carcass protein estimated in the following manner. In each experiment a control group of depleted animals was maintained on the low protein ration through the experimental period. This group was sacrificed with the others. The mean quantity of protein found in the carcasses of these animals was subtracted from the quantity determined in each of the repletion groups. The value thus obtained included the quantity of protein lost by the control group, that is, the wear and tear protein loss. This quantity we have determined and subtracted from the apparent gains of the animals in the repletion groups in order to obtain the measure of protein fabrication over and above that which merely replaced the wear and tear losses.

In order to include all, or practically all, of the protein fabricated in the experimental interval, the increase in the liver protein was added to that in the carcass protein. Increases in other compartments not included in the car-

Fig 3 —The influence of simultaneous variation of protein and caloric intake levels on protein utilization

cases were not of sufficient magnitude to necessitate their addition. Recorded rates of gain therefore represent for practical purposes all of the protein fabricated into body tissue, exclusive of that used for maintenance.

Fig 1 demonstrates the influence of variation in caloric intake upon protein utilization, the protein intake remaining approximately constant. At the lowest level of caloric intake (560 Cal per square meter per day) protein utilization was very poor (0.3 Gm per kilogram per day). With increasing caloric intake, protein utilization rose until a maximum was reached at an intake level of 1,240 Cal per square meter per day. Beyond this point there was no additional utilization of protein despite the fact that the caloric intake increased up to 1,840 Cal per square meter per day.

The effect of varying the protein intake at a constant caloric intake is demonstrated by Fig 2. As the protein intake was raised from 2.5 to 14.8 Gm per kilogram per day, protein utilization rose. The rise was almost linear up to about 6 Gm per kilogram per day. Beyond this point the rate of protein utilization became progressively less. Nevertheless, at the highest level of intake the ceiling of utilization had not yet been reached.

What occurred when increasing quantities of the same diet were fed to the depleted animals is shown in Fig 3. In this situation there is a constant ratio of protein to energy in the diet, the levels of protein and caloric intake varying

Fig 4 —The influence of caloric intake at a constant protein intake on the rate of fabrication of carcass fat and protein by depleted rats

together. Under these circumstances the rate of protein utilization increased with increasing diet intake. Looked at from another point of view, when the quantity of diet was restricted, the rate of protein utilization was restricted. It is evident from the data that the limitation in the rate of protein utilization was not the summation of the effects of the restriction of both protein and energy intakes, and the restriction of utilization at any point was no greater than the maximum restriction induced by the restriction of the protein component alone.

CONSTANT CALORIC INTAKE
AV 1630 CAL /M²/DAY

Fig 2 —The influence of level of protein intake on protein utilization

Fig 3 —The influence of simultaneous variation of protein and caloric intake levels on protein utilization

Our observations on protein depleted animals are in agreement with those cited on patients and growing animals. Thus there is a restriction in the utilization of a constant quantity of protein when the calorie intake falls below a critical value of about 1,240 Cal per square meter per day. Furthermore, elevation of the calorie intake above this level does not increase the effectiveness of the dietary protein for the synthesis of new tissue. It is of interest in this connection that the critical calorie value observed by Bosshardt and co workers⁸ with the growing rat was approximately 1,250 Cal per square meter per day.

What is the significance of this critical calorie value? It is possible to elucidate the nature of the composition of this 1,240 Cal per square meter per day by breaking it down into its component parts: (a) energy used for maintenance, (b) energy for physical work, (c) energy for tissue fabrication (d) energy stored in the form of new tissue (that is as fat and protein) and (e) waste energy in compounds excreted but not completely burned. From crease analysis data and food intake energy balances can be constructed. Thus the animals receiving a total energy allowance of 1,240 Cal per square meter per day stored 323 Cal per square meter per day as new tissue. The difference between the total intake and the energy appearing as new tissue represents the quantity consumed for energy and wasted. Therefore the animals must have consumed and wasted a total of 917 Cal per square meter per day. From Table III it is evident that the animals which received 560 Cal per square meter per day were able just to maintain themselves during the fourteen day period. It appears justifiable therefore to take this as an approximation to the minimal maintenance energy requirements. The difference between the total energy consumed (917 Cal per square meter per day) and the energy used for maintenance (560 Cal per square meter per day) represents the energy used to construct new tissue plus waste energy, in this case 457 Cal per square meter per day.

The quantity 1,240 Cal per square meter per day therefore appears to represent the energy allowance which will supply the maintenance needs of the animal with sufficient excess to allow for maximal utilization of ingested protein for tissue synthesis. At caloric intakes below the critical level the animal must resort to burning protein for purely energy purposes. As a consequence the restriction of caloric intake below the critical point has the same net effect as a restriction of the protein intake.

Fat and protein synthesis in the depleted animal are partly independent. At low caloric intake levels both fat and protein storage are proportional to the caloric intake. At caloric intake levels above the minimum necessary for maximum protein fabrication, fat and protein metabolism are essentially independent (Fig. 4). A partial independence of the fat and protein metabolism has been observed in human beings.¹⁰ It was found that obese individuals on protein intakes of 1 to 1.5 Gm per kilogram per day and on caloric intakes 30 per cent less than estimated basal needs lost weight but remained in nitrogen equilibrium. Nonobese individuals on such a regime not only lost weight, but also had negative nitrogen balances. Thus it appears that the normal organism requires a certain quantity of fatty tissue in addition to nonfat tissue, but excessive quan-

ties of fat are not only unnecessary but also probably undesirable and can be dispensed with without sacrificing more needed tissues. Some fat gain is necessary in the rehabilitation of depleted individuals for the purpose of building up energy reserves. Excessive fat gain is probably to be avoided since it appears to do little but place an extra physical strain upon the organism and in addition is economically wasteful. Therefore, *adequate* but not excessive caloric intake is the aim in convalescent and rehabilitation feeding.

The statement has been made that nitrogen *balance* can be maintained on a low caloric intake for short periods of time by giving relatively large amounts of protein.⁹ Our findings agree with this. Thus at a low caloric intake (560 Cal

Fig. 6—The rate of protein utilization for tissue synthesis at different levels of protein intake — Adult depleted rats -- growing rats after Barnes and coworkers.¹³

per square meter per day) and a protein intake of 9 Gm. per kilogram per day very low degrees of nitrogen utilization were found, similar to those obtained by Elman and associates⁹ in dogs. But it is obvious from our observations that this is a highly inefficient procedure in terms of nitrogen utilization. Moreover, in a debilitated patient the desired result is not the achievement of mere nitrogen equilibrium, but rather the high degrees of nitrogen retention which go with the fabrication of significant quantities of new tissue.

Long ago it was found that the rate of gain of body weight in growing animals increases as the protein intake is increased.¹¹ Forbes and co-workers¹ investigated this problem further with careful studies of nitrogen and energy

metabolism. Unfortunately, their lowest protein intake level was 7 Gm per kilo gram per day so that they have no data on the important lower levels of intake. More recently, this problem has been reinvestigated by Barnes and colleagues.¹³ These investigators fed protein at various intake levels to growing rats, keeping the energy intake approximately constant. They did nitrogen determinations on the carcasses. Their data, recalculated and plotted in Fig. 6 along with the observations from Experiment 2 described here, are in excellent agreement with ours derived from the adult protein depleted rat.

This agreement becomes all the more significant when one considers the fact that the animals used in the two experiments differed both in age and size, one group being protein depleted. A fundamental relationship appears to exist between the intake level of protein and the rate of protein utilization for the fabrication of tissue in the growing animal and in the adult protein depleted animal undergoing repletion. Putting all of the foregoing facts together, we infer that the fabrication of a kilogram of new tissue in a growing animal and the reconstruction of a kilogram of tissue in an animal which has lost tissue due to protein deficiency demand similar quantities of structural material and similar constructing energies.

This does not imply that the quantitative requirements and the behavior of tissue synthesis in relation to protein intake are the same under all conditions, because certain things may modify the rate of utilization of protein. Thus as an animal approaches its growth maximum, the rate of utilization of protein for synthesis of new tissue declines. In the face of injuries such as burns, fractures, or infections, there also is a marked decrease in the rate of tissue synthesis.¹⁴ But other things being equal, the rate of utilization of a high quality protein for synthesis of new tissue increases with increasing levels of protein intake, providing the caloric intake is adequate to supply both the basal energy needs of the organism and the energy needed for synthesis, including that stored in new tissue.

The question arises as to how far these data derived from the rat are applicable to human beings. In a later paper, evidence will be presented demonstrating the fundamental similarity of the protein fabricating mechanisms in these two groups of mammals.

SUMMARY AND CONCLUSIONS

Experiments are described which were designed to elucidate the interrelationships between protein intake and energy intake as they affect the utilization of protein for tissue synthesis in standard protein depleted rats.

The following conclusions are drawn:

Restriction of the caloric intake below a certain critical level restricts the utilization of ingested protein for the fabrication of tissue. Furthermore, an increase in caloric intake above this critical level does not augment the rate of utilization of a given quantity of protein above the maximum attainable with the particular protein fed under the particular circumstances of feeding (that is, level of protein intake, needs of animal, and so on). This critical level ap

pears to be approximately 1,240 Cal per square meter per day, and constitutes the energy necessary to cover the needs for maintenance, storage, tissue synthesis, and waste

Increasing the caloric intake above the critical level needed for maximal rates of protein synthesis results in increased rates of body weight gain due largely to deposition of fat

With an adequate caloric intake the rate of utilization of protein is a function of the level of intake and, in general, utilization rises with increasing intake

The fabrication of a kilogram of tissue in a growing rat and the reconstruction of a kilogram of tissue in the adult protein-depleted rat demand the same quantities of structural material and similar constructing energies

THE DYNAMICS OF PROTEIN METABOLISM

II THE RELATIONSHIP BETWEEN THE LEVEL OF PROTEIN INTAKE AND THE RATE OF PROTEIN UTILIZATION BY PROTEIN DEPLETED MEN AND RATS

LARL P. BENDITT, M.D., ROBERT L. WOOLRIDGE, M.A. AND ROBERT STEPTO, M.D.
CHICAGO, ILL.

INTRODUCTION

TODAY, perhaps as never before, there is urgent need of more knowledge concerning basic principles of nutrition. Speedy rehabilitation of underfed persons with only limited quantities of available food demands the most judicious use of the food supply. To accomplish this we must know what part the major components of the diet, principally protein and energy, play in the fabrication of body tissue.

In a previous paper¹ we examined the effects of varying caloric and protein intakes upon the utilization of dietary protein for tissue synthesis by protein depleted and growing rats. It was demonstrated that on an otherwise adequate diet a certain minimum level of caloric intake at a given protein intake level was needed to insure maximum tissue synthesis. Above this minimum level, increases in the caloric intake did not further augment protein utilization. Furthermore with an adequate caloric intake the rate of protein utilization increased with increasing protein intake. These relationships were found to be similar in the growing rat and in the adult depleted rat during repletion. Such observations led us to examine data from the literature on human beings and to compare them with our data on rats. After doing so, it was found necessary to extend the rat experiments to include protein intake ranges commonly used and feasible in human feeding.

The following evidence demonstrates that animal experiments can be used as qualitative and quantitative guides in elucidating the problems of human nutrition providing the appropriate common denominators are employed in making the extrapolations from one species to another. Furthermore with the combined data available on men and animals it is possible to attack intelligently the problem of constructing more efficient diets for starved and convalescing human beings.

METHODS AND MATERIALS

Observations on human beings providing simultaneous data on body weight, height, caloric intake, protein intake, protein source, nitrogen retention and the degree of weight loss were sought from the literature. Although most such studies deal with diseased indi-

From the Department of Pathology, University of Chicago.

The subject matter of this paper has been undertaken in cooperation with the Navy Department Office of Naval Research and with the Committee on Food Research of the Quarter Master Food and Container Institute for the armed forces. The opinions or conclusions contained in this report are those of the authors. They are not to be construed as necessarily reflecting the views or indorsement of the War Department.

The work has also been aided by the Douglas Smith Foundation for Medical Research of the University of Chicago and the National Live Stock and Meat Board.

Received for publication Jan. 3, 1948.

individuals, one study was found² which dealt with the rehabilitation of otherwise healthy individuals suffering from severe malnutrition. Many otherwise good data had to be discarded because one or more important measurements were absent, particularly those of body weight and height. Moreover, many reports had very brief and incomplete accounts of diet composition.

Before we could compare the observations on rats with those on men it was necessary to have some common units of measurement. Obviously one could not compare directly the daily nitrogen excretion for a man of the order of 10 Gm with that of a rat of the order of 0.1 gram. Expressed in absolute terms, each of these values has significance only in relation to the particular animal from which it was obtained. Units which compare quantities on the per animal basis are biologic units in a sense, but are not broad units which admit comparisons between animals of such widely different size as a rat and a man, nor even between large and small animals of the same species.

Assuming that the basic mechanisms of protein synthesis are the same for all of the mammalian species upon what rational basis can we compare them? It has been demonstrated that energy consumption is approximately proportional to the surface area for a wide variety of mammals.³ Basal nitrogen excretion in several mammalian species including man has been demonstrated to be proportional to the basal energy requirement.⁴ Therefore it appears reasonable to compare the maintenance nitrogen requirements of different animals on the basis of surface area. Such a procedure is not necessarily valid when we are dealing with the construction of new tissue or the reconstruction of depleted tissue. What is the reasonable basis of comparison for feeding in this situation? The ingestion of protein under the conditions of synthesis and storage of new protoplasm falls in a class with many other chemical reactions. The chemist has long expressed additions to synthetic systems in terms of grams, moles, or equivalents of chemical substances per unit of fluid volume or mass. Viewing a kilogram of active protoplasm as such a chemical system, it appears rational to designate additions of protein offered to the system as so many grams per kilogram per day and likewise to compute protein retained and incorporated into the system in similar terms.

Energy intake is another measurement which must be reduced to common terms for comparative purposes. There is an old precedent for this in that basal metabolism has been expressed for many years in terms of calories per square meter of body surface per unit of time. We will not now discuss the significance of this relationship (see Brody⁵), but we have assumed its validity and computed the caloric intakes as calories per square meter of body surface per day (Cal per square meter per day). For computation of the surface area of rats Lee's formula⁶ was used, and for the human being, the tables of Dubois.⁶

In the experimental observations, adult male albino rats (Sprague Dawley) weighing initially 288 to 350 grams were depleted of 15 to 25 per cent of their body weight in a period of five weeks on an essentially protein free diet.⁷ At the end of the depletion period they were placed in individual metabolism cages. Five diets were constructed offering approximately 0, 1, 2, 3, and 4 Gm of protein per kilogram of body weight per day. The basic composition of the diets was the same as that of the standard repletion diet used in this laboratory.⁸ Isodynamic replacement of the carbohydrate by calculated quantities of protein furnished the required protein levels. The protein was a half and half mixture lactalbumin* and casein†. Fifteen grams of each ration were offered daily to each animal supplying it with 48 calories or between 1,200 and 1,400 Cal per square meter per day. Five animals were used and the diets were rotated from day to day (Table II). The order of rotation for each animal was different. Daily collections of urine, feces, and waste food were made and the rats were weighed. The waste food was weighed

*Borden's No. 1542

†SMACO vitamin test, General Biochemicals Inc.

and pooled with the urine and feces for Kjeldahl nitrogen analyses. From these determinations the diet analyses and the food intake data the nitrogen balances were computed. Caloric intake was computed from the food intake using the conventional caloric equivalents.

A second experiment was performed using six animals and the 0.1 and 4 Gm per kilogram per day levels of protein intake along with three other diets of varying caloric value and bulk. The procedure used was similar to that described except that the feces were analyzed separately from waste food and urine. Throughout these experiments food waste was minimal averaging 3 per cent and never over 7 per cent of the total offered.

OBSERVATIONS

A series of observations on the effects of various diets in the repletion of a group of severely starved but otherwise healthy men was published by von Hoesslin in 1919.² By comparison with normal height and weight tables³ we estimated that the subjects had lost between 21 and 29 per cent of their body weight prior to the start of the tests. The repletion diets contained protein from both animal and vegetable sources of which 23 to 58 per cent was animal protein.

6	51.5	2650	1.7	0.60

Both caloric and protein intakes were varied and the nitrogen retention under the different conditions was observed. Groups of five men were fed each diet and the period used to test a single diet varied from four to seven days. A summary of the recalculated data is presented in Table I and in Fig. 1 protein utilization is plotted against protein intake. The data in the table demonstrate that at a constant protein intake (1.7 Gm. per kilogram per day) increasing the caloric intake from 1350 to 2650 Cal. per square meter per day had no influence upon protein utilization. On the other hand Fig. 1 demonstrates that protein utilization is proportional to protein intake over the range of protein intake studied.

FIG 1—The influence of the level of protein intake on the rate of protein utilization by convalescent adult and growing human beings

Observations were collected on a group of patients suffering from wasting diseases principally cancer. Their usual hospital diet was supplemented with a protein hydrolysate (casein) administered intravenously and nitrogen retention was studied. We have recalculated these data of Altshuler and co-workers⁹ for nine cancer patients and plotted them in Fig. 1. The chart demonstrates that protein utilization increases proportionally on the average to the protein intake. Examination of the whole of the observations on the cancer patients by the method of partial correlations brings out the fact that over the entire range of calorie intake used, from 570 to 1,700 Cal per square meter per day, calorie intake had no significant influence upon protein utilization whereas protein utilization had a highly significant correlation with protein intake.

Patients convalescing from gastrectomies for peptic ulcer were fed through orogastric tubes by Mulholland and Co. Tins and colleagues^{10, 11}. These patients received protein ranging from 2.4 to 4.2 Gm per kilogram per day and calorie intakes between 1,100 and 2,700 Cal per square meter per day. The protein source was an enzymatic hydrolysate of casein. In Fig. 1 the recalculated data on these patients have been plotted and demonstrate that protein utilization was proportional to the protein intake.

The protein metabolism of a healthy 2-month-old infant was studied by Hoobler¹. The intake of cows' milk protein was varied from 2.2 to 10.9 Gm per kilogram per day and the calorie intake was maintained between 1,040 and 1,240 Cal per square meter per day with the exception of one period when it rose to 1,570 Cal per square meter per day. The recalculated observations (Fig. 1) demonstrate that this young infant utilized ingested protein at a rate proportional to the protein intake. Gordon and associates¹² studied the protein metabolism of premature infants. Their data (Fig. 1) also demonstrate that the protein was utilized at a rate proportional to the level of protein intake and a little less efficiently at the higher levels of intake than it was utilized by the full-term infant.

Wang and co-workers^{14, 15} made extensive studies of the metabolism of normal and undernourished children. Their data show (Fig. 1) that the utilization of ingested protein nitrogen by both groups of children was proportional to the protein intake. The protein was mixed but largely of animal origin. They found that children who were 20 per cent or more below the normal weight standards utilized the protein a little more efficiently than less underweight and normal children¹⁵. The absolute proportion of ingested protein retained by Wang's subjects averaged substantially less than that retained by the normal infant or the starved adults. Metabolism of nephrotic children at protein intake levels varying between 0.6 and 4.8 Gm per kilogram per day was studied by Farr¹⁶. His data (Fig. 1) indicate that even these children utilized increasing quantities of protein as the protein intake was increased up to about 3 Gm per kilogram per day but beyond this as the intake was further increased the utilization fell sharply.

In Table II are the data derived from the experiments with rats and in Fig. 2 the rate of protein utilization is plotted against the rate of protein intake. It is obvious that over the range of intake studied the rate of utilization of a

high quality protein is proportional to the level of protein intake, providing the calorie intake is adequate. Comparison of these data with those of Experiment 2 in the preceding publication¹ shows that the two follow the same general pattern. Utilization of protein in the present experiments appears to be at a somewhat higher level than in the preceding one. This may be due in part to the fact that the periods of observation here were shorter, and that therefore the avidity of the tissues for protein remained closer to maximal, whereas with the fourteen day experiments the growth potential was already significantly decreased toward the end of the period of observation.

Fig. 1.—Utilization of ingested protein by protein depleted rats on an adequate caloric intake at varying levels of protein intake

DISCUSSION

The foregoing observations demonstrate that the protein depleted and the growing animal, man or rat given an adequate caloric intake utilize protein at a rate which is proportional to the rate of protein intake. For man a similar pattern of reaction is apparent not only in convalescence from starvation alone but also in convalescence from certain debilitating diseases. The similarity in the performance of the depleted rats and the starved men is strikingly evident when one compares Fig. 2 with Fig. 1.

At first glance the similarity in response to protein ingestion of these two species of mammals of such different size and external characteristics seems remarkable. These facts when compared with some of the many other observations on mammals appear less startling. They become not unique but part of a great body of evidence accumulated over many years which points to the conclusion that the basic mechanisms underlying the organization and functioning of the tissues of the different species of animals are fundamentally similar. Let us examine a little of the evidence from the biochemical standpoint having in mind principally, a comparison of the rat and the human being. Body temperatures of rats and men are almost identical and their basal metabolic rates do not differ greatly. In broader terms the basal energy requirements of animals varying in size from the mouse to the elephant have been found to be proportional to a function of the body mass which approximates mathematically

the surface area.³ The basal nitrogen excretion is related to the basal metabolism, thus rat, rabbit, guinea pig, man, and swine have been shown to excrete in urine an almost identical quantity of nitrogen per basal calorie per day.⁴ The same amino acids, with the possible exception of histidine,¹⁷ appear to be indispensable for the growth and maintenance of the rat and of man.^{18, 19} Moreover we have evidence which suggests that the essential amino acids are needed in similar relative proportions in the two species for maintenance and for growth.¹⁸ Viewing the matter broadly, there is a general quantitative, as well as qualitative, pattern into which rats and men as well as other mammals fit.

Von Noorden acknowledged the broad problem of the relationship of the level of protein intake and the caloric intake to the rate of repletion of lost tissue.²⁰ He outlined the types of experiments needed to settle the question, but presented evidence from only a single type of experiment, namely, that in which approximately the same quantity of protein per kilogram of body weight was fed per day to patients convalescing from debilitating infections while the caloric intake was varied. He concluded from these observations that high caloric intakes were more favorable than high protein intakes in inducing more rapid rates of rehabilitation.

Recently Keys has emphasized the efficacy of high caloric intakes to further rehabilitation in starved men.²¹ He states that, "In relief feeding, calories are of overwhelming importance. Within reasonable limits every increase in calories is associated with an increased rate of recovery." He states further that, "Extra vitamins and proteins had very little apparent effect on the rate or course of recovery." The evidence which we have presented is not in accord with these statements, and demonstrates that while caloric intake is a factor, it is not the only factor. Moreover, with an adequate caloric intake, the level of protein intake and the quality of the protein become the limiting factors.

The role of caloric intake in problems of nutrition has been vastly overdrawn for as Cathcart²² has stated, "We do not live on calories. Caloric value is simply a very convenient physical standard for the assessment of diets but merely because such a standard has proved of great utilitarian value there is no real justification for placing this standard as the foundation stone of hypotheses framed to offer an explanation of cellular activity. Many writers are obsessed with the idea of the calorie, forgetting that the organism is certainly not a heat engine. It is perfectly true that calories are a measure of heat, but it must not be forgotten that we do not consume actual heat units but only potential heat-giving substances which can eventually be degraded to the form of heat and be measured as such. The thermal aspect of nutrition is unduly stressed, for, while heat may be a necessary product of tissue activity, it is after all a by-product."

The aim when feeding sick, convalescent, starved, and growing individuals is not the mere maintenance of nitrogen equilibrium but the storage of significant quantities of protein as new tissue. The preceding observations demonstrate clearly that certain desirable conditions must be satisfied to attain this goal. The conditions are as follows: (1) caloric intake must be adequate to cover needs for maintenance, physical exertion, tissue synthesis storage and

waste, (2) a protein of high biologic value must be fed, (3) the protein must be fed in excess of the quantity needed to maintain nitrogenous equilibrium and in general the higher the level of protein intake the greater the rate of synthesis, (4) other dietary essentials (vitamins minerals and so on) must be adequate

With these general propositions before us we are in a position to make more specific estimates of caloric and protein intakes for convalescence. But first we must clarify one further point. It has been customary to compute diets on the basis of total caloric content and protein content. The total caloric content has practically always included the caloric equivalent of the protein. In convalescence from starvation of any origin the maximal utilization of protein for tissue reconstruction is desired. Therefore it appears rational to include protein in the computations both as a source of amino acids for tissue fabrication and as a source of fuel for energy consuming reactions. The rational procedure is to feed protein as a source of building material and compute the energy value of the diet independent of its protein content on the basis of its carbohydrate and fat content.

An adequate caloric intake for a convalescent man can be estimated from considerations of the known basal requirements, requirements for physical exertion, protein synthesis and waste. For an average sized man (surface area 1.7 square meters) afebrile and at bed rest the estimate is 2,600 calories per day or 1,500 Cal per square meter per day.* Such an allowance represents not the absolute minimum but is comparable to the standard ration used by us in many animal experiments which allows approximately 1,460 Cal per square meter per day of nonprotein energy.

The animal data¹ indicate that a protein intake level of 10 Gm per kilogram per day or more would provide better rates of protein synthesis than 2 or 4 Gm per kilogram per day. Unfortunately it is not possible to feed adult human beings at this level. The reason for this becomes clear if one compares the per kilogram energy consumption of rats and men. The relatively large surface to mass ratio of the rat allows a 10 Gm per kilogram per day protein intake to represent only a fraction of the total caloric intake (about one eighth) whereas this level of protein intake would represent almost the entire daily caloric needs of a man. But the data indicate that a man can easily use up to 4 Gm per kilogram per day. Protein intakes of the order of only 1 Gm per kilogram per day will be ineffective in inducing significant degrees of protein storage. While this level of protein intake is the commonly accepted standard for maintenance of nitrogen equilibrium in a healthy individual it is inadequate for the depleted

The estimate was arrived at in the following manner. Basal requirements of a normal man are approximately 1,000 Cal per square meter per day and a starved man needs even less. For the activity associated even with bed rest 30 per cent of the basal requirements were added. From thermodynamic considerations it has been shown²² that the peptide bond contains a free energy equivalent of 7.5 calories per mole. Assuming only a 10 per cent efficiency in the biologic synthesis it would take 83 calories to synthesize 100 Gm of protein. To allow for the synthesis of 100 Gm of protein with some excess .00 calorie were added for this factor. Excluding waste energy the needs for the described situation are $1.7 \times 1.00 + .00 = 2,410$ calories. According to Rubner²³ about 8 per cent of the energy intake is lost in the feces therefore 190 calories were added for this factor totalling 2,600 calories.

individual in whom nitrogen must be stored. We cannot overemphasize the fact that there is a fundamental difference between the maintenance of the equilibrium state in the fully grown and healthy adult and the construction of new tissue in the depleted or growing individual. In order to obtain good rates of tissue synthesis under these latter conditions it is necessary to feed at protein intake levels of the order of 2 to 4 Gm. per kilogram per day. An examination of the data (Fig. 1) demonstrates that the higher protein intake levels have two advantages: first, a greater absolute rate of protein storage, and second a higher gross efficiency of protein utilization.

SUMMARY AND CONCLUSIONS

For the purpose of evaluating the respective roles of the level of caloric intake and the level of protein intake in the restoration of protein stores of depleted animals, we have presented further experiments on rats and a re-evaluation of observations from the literature on men. From these data the following conclusions are drawn: (1) In both groups of mammals with protein intakes ranging from 0.5 to 4 Gm. per kilogram of body weight per day the utilization of protein for tissue synthesis is proportional to the protein intake. (2) The rate of protein utilization is independent of the caloric intake at caloric intake levels above those which supply the needs for maintenance, synthesis, storage, and waste. The estimated nonprotein energy needs for an adult male man at bed rest in the absence of other metabolic stimulants is approximately 1,500 calories per square meter of body surface per day. (3) Since the therapeutic goal is not the mere maintenance of nitrogen equilibrium but the fabrication of significant quantities of body protein, protein intake levels of 2 to 4 Gm. per kilogram per day are demanded for the rapid rehabilitation of a depleted person. At these levels there is both a higher gross efficiency of protein utilization and a greater absolute rate of protein gain.

THE DETERMINATION OF THE NITROGEN BALANCE INDEX OF A NEW LYOPHILIZED AMINO ACID PREPARATION IN PROTEIN-DEFICIENT PATIENTS

WILLIAM S. HOLTMAN, M.D., Ph.D., DONALD D. KOZOLL, M.D., W. T. MOK, M.D.
KARL A. MEYER, M.D. AND HANS POPP, M.D., Ph.D.
Chicago, Ill.

PROTEIN products and protein hydrolysates intended for human nutrition have their principal usefulness in the repletion of protein deficient patients. The criterion for clinical acceptability of such a product has been its ability to produce positive nitrogen balance in protein deficient subjects. The quantity required for positive balance must be of the same order as that of the mixture of proteins in the common foods. If a much greater quantity is required it is recognized that the biologic value of the investigated product is relatively low, at least under the conditions of administration utilized.

Yet it has been increasingly clear from nitrogen balance experiments that human subjects with protein deficiency differ greatly from each other in the nitrogen intake of a particular protein required for nitrogen equilibrium, even when such subjects are chosen from an apparently homogeneous group. For example, in a nitrogen balance study of a casein hydrolysate in this laboratory some subjects came into positive balance with a daily intake of 60 Gm. of amino acids others with 90 Gm. and still others only after 120 grams. An occasional patient could not be brought into balance with as much as 135 Gm. of amino acids equivalent to 16.9 Gm. of protein nitrogen. Comparable findings were obtained in the study of an oval albumin derivative.¹ The calculation of the *average* requirement of a particular protein in experiments such as these is justifiable only if the number of experiments is large and if the deviations from the average are not too great. The utilization of such averages for comparison of one product with another is obviously fraught with danger.

Recent feeding experiments with protein depleted dogs by Allison and co-workers^{2, 3} have demonstrated that even laboratory animals under careful supervision show wide variations in protein requirements for nitrogen equilibrium. These investigators have been able to show that the nitrogen intake at equilibrium depended upon the nitrogen excretion on a protein free diet, the latter excretion being a measure of the so called endogenous protein metabolism. The lower the nitrogen excretion (NE_e) on the protein free diet the lower was the requirement for equilibrium. If the nitrogen balance (NB) obtained on successive nitrogen intakes the latter being calculated as absorbed nitrogen (AN), was plotted against the absorbed nitrogen, a curve was obtained which in the region of negative and low positive nitrogen balance was a straight line.

From the Hektoen Institute for Medical Research of the Cook County Hospital and the Departments of Surgery of the Cook County Hospital and the Cook County Graduate School of Medicine

Aided by a grant from The Biochemical Division, Interchemical Corporation, Union N. J.
Received for publication Oct. 23, 1947

The equation for this relationship was $NB = K (AN) - NE_0$. The value K was the slope of the line and it was found to be a measure of the biologic value of the protein used in the study. It tended to be a constant for any given protein even when the nitrogen intake at equilibrium varied considerably. Thus the calculation of K appeared to be a much better characterization of the biologic value of the protein than the nitrogen requirement at nitrogen equilibrium. The values for K were usually less than 1; the nearer to 1 they were the greater the fraction of absorbed nitrogen that was retained. Casein for example was found to have a K value of about 0.80. Allison has called K the nitrogen balance index.

It appeared to us during the course of a study of the clinical acceptability of a new casein hydrolysate prepared for parenteral use, that the methods and equation of Allison might be applicable to nitrogen balance studies in human subjects. The present investigation was therefore undertaken to find out whether the nitrogen balance index of this amino acid preparation tended to be constant in the nitrogen balance experiments with twenty patients with chronic protein deficiency and whether such an index was a better criterion of biologic value than the nitrogen intake at nitrogen equilibrium.

METHODS

The study was carried out in a metabolic unit staffed twenty-four hours a day by nurses specifically chosen for this function. The urine specimens were collected for each twenty-four hour period in closed bottles containing toluene and were sent each day to the laboratory for analysis. The subjects were under constant supervision to avoid the loss of specimens. A further check was the determination of the daily creatinine excretion.

Since none of the twenty patients chosen had any difficulty taking oral alimentation this avenue was utilized as a means of furnishing an adequate intake of calories from carbohydrate and fat. The oral dietary was designed to be virtually free of protein so that the only significant source of nitrogen would be the parenterally injected amino acids. However, the food orally ingested could not be made rigidly free of nitrogen as might be possible with laboratory animals or volunteer human subjects. The dietary consisted of a carbohydrate drink*, tapioca and cornstarch puddings, orange juice, tomato juice and a puréed leafy vegetable. Since the amount of nitrogen in the foods chosen was low (between 350 and 500 mg) and since it was derived from proteins of poor absorbability and poor biologic value, the error involved in the inclusion of this nitrogen source was probably of no consequence. It was probably no higher than the nitrogen lost in perspiration, even though the studies were carried out in cool weather and was therefore not included in the calculation. The oral carbohydrate and fat plus the intravenously injected dextrose furnished approximately 2,000 calories per day, but slight variation above or below this quantity could not be avoided.

The amino acid preparation under study was a casein acid hydrolysate fortified with tryptophane and prepared as a lyophilized solid in 850 cc flasks†. The nitrogen content and the percentage composition of essential amino acids in the preparation are shown in Table I. A substantial portion of the glutamic and aspartic acids present in the original hydrolysate had been removed by a special process. Each flask contained 60 gm of the lyophilized solid which could be reconstituted to a perfectly clear solution with water, physiologic saline or dextrose saline solutions. The solution could be made up in 5

lnd. The carbohydrate used was Carbo-cel furnished by H. W. Kinney and Sons, Columbus.

7.5, or 10 per cent concentrations of the amino acids. Most of the injections were made with a 5 per cent solution at a rate between 50 and 60 drops per minute in order to make sure that there would be no vomiting. But even when the 10 per cent solution was utilized in these and other experiments, if this rate was not exceeded nausea or vomiting seldom occurred. Repeated injection in the same vein tended to produce thrombophlebitis, as has been found with other protein hydrolysate preparations used. But this circumstance could be mitigated by frequent change of the veins utilized and by starting with the most peripheral veins and proceeding cephalad. The needles used were No. 19 gauge and were introduced with a minimum of trauma to the veins.

TABLE I CHEMICAL ANALYSIS OF AMINO ACID PREPARATION USED IN THIS STUDY
(AMINO ACIDS, I.C., LYOPHILIZED)

	(%)
Nitrogen	
Total	13.4
Alpha amino	10.0
% Alpha amino nitrogen of total nitrogen	75.0
Essential amino acids (by microbiologic assay)

Methionine	3.0
Phenylalanine	5.5
Threonine	5.0
Tryptophane	0.5*
Valine	7.3
Moisture	12.0
Ash	0.9

*One per cent DL-tryptophane added

All patients were first placed on the protein free diet for a period of three days or more to establish the endogenous nitrogen excretion level. Then daily infusions of amino acids were given in addition to the oral alimentation in quantities known not to produce positive balance. After three or four days of this regimen, the quantity of amino acids was further increased and maintained at the new level for three or more days. With successive increases a nitrogen balance was achieved that was barely positive. Further increases were then made at a more rapid rate to determine, if possible, the maximal level of utilization.

Careful attention was paid to the vitamin requirements of the patients. Ascorbic acid was given in doses of 500 mg per day, thiamin and other members of the vitamin B complex were given as Betulin Complex,* one cc of which provided 5 mg thiamin chloride, 2 mg riboflavin, 75 mg nicotinamide, 25 mg calcium pantothenate, and 5 mg pyridoxine hydrochloride.

Quantitative analyses of the nitrogen content of blood, urine, feces, and foods as well as that of the hydrolysate were carried out by the photometric micro Kjeldahl method described by Hoffman and Osgood.⁵ They were frequently checked by macro Kjeldahl determinations involving distillation and titration. For stool analysis, the preparations were first homogenized in water by the addition of concentrated sulfuric acid, as suggested by Peters and Van Slyke.⁶ Plasma volumes were estimated from a single ten minute plasma sample after the injection of 10 mg of Evans blue as described by Greger.⁷ A calibration curve was made in each analysis with the control serum. To avoid variations in the fat content of the control and dye containing samples, the tests were made at least twelve hours after the previous meal or infusion of amino acids. Hematocrit determinations were made on heparinized blood by the method of Wintrobe and Landberg.⁸ Urine and stool analyses were made daily, blood analyses including plasma volume estimations were made usually at weekly intervals, at which time the patient was weighed.

RESULTS

Minimal Requirements for Positive Nitrogen Balance—Positive nitrogen balance was achieved in nineteen of the twenty subjects studied. The data are shown in Table II. Patient 7, who had a carcinoma of the esophagus had not come into positive nitrogen balance on an intake of 182 mg nitrogen per kilogram per day. This patient might possibly have achieved positive balance at a higher level of intake, but he could not be kept on the study any longer. The remaining nineteen patients showed a wide variation in the intake needed for positive balance, ranging from 57 to 476 mg nitrogen per kilogram daily. But these values had little meaning since the levels of positive balance achieved with these quantities varied considerably. Much more significant were the nitrogen intakes required for each nitrogen equilibrium. These quantities could

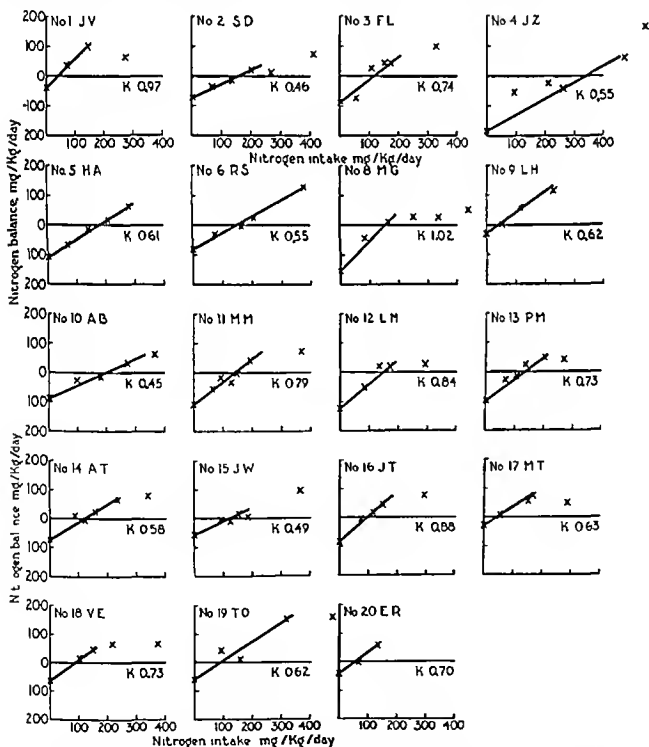

Fig 1—Nitrogen balance curves in nineteen subjects in whom positive nitrogen balance was achieved

be estimated only by interpolation from the curves obtained by plotting nitrogen balance against nitrogen intake (Fig 1). Of the nineteen curves, thirteen were reasonably good straight lines in the region of negative and low positive balance, the remaining six required some arbitrariness for the establishment of straight lines. The range of nitrogen intake levels required for nitrogen equilibrium in all nineteen cases was 42 to 340 mg per kilogram per day. The arithmetic mean was 129 mg and the standard deviation, 66 mg, which was 51 per cent of the mean. If only the thirteen good cases were chosen, the range was 42 to 197 mg per kilogram per day, with a mean of 122 mg and a standard deviation of 48 mg, or 39 per cent of the mean. Thus it was evident that though the range of nitrogen intakes required for nitrogen equilibrium was narrowed if the proper experiments were chosen, that range was still broad.

Nitrogen Balance Index—As has been stated, thirteen of the nineteen nitrogen balance curves were straight lines in the region of negative and low positive nitrogen balance. Even the remaining six curves did not show great deviations from a straight line, but their exact slopes were difficult to determine

Fig 2—Relation of nitrogen intake at nitrogen equilibrium to nitrogen excretion on a protein-free diet (K is the ratio of nitrogen excretion on a protein free diet to the nitrogen intake at nitrogen equilibrium)

These straight-line curves obeyed the equation shown earlier. (Nitrogen intake in these experiments was equal to absorbed nitrogen if the small amount of ingested nitrogen which was absorbed from the intestine was ignored.) Thus these experiments confirm in human subjects with protein deficiency produced by disease the findings of Allison and Anderson³ for dogs with induced protein deficiency.

The K values for the equations of the curves shown in Fig 1, which were the slopes of these curves and which were most easily calculated from the ratio of nitrogen excretion on a protein-free diet to the nitrogen intake at nitrogen

equilibrium, ranged from 0.45 to 1.02. The mean was 0.68 and the standard deviation was 0.16, or 24 per cent of the mean. In the thirteen cases with good straight line curves K ranged from 0.45 to 0.88 and the mean was 0.66 with a standard deviation of 0.13 or 20 per cent of the mean. In consideration of the difficulties of nitrogen balance studies in such patients as well as the many potential sources of error in the nitrogen analyses the K values arrived at in these experiments showed remarkably small deviation from the average. These findings also offered corroboration of Allison's conclusion that the K values tended to be constant for any particular protein. This approximate constancy is graphically illustrated in Fig. 2 where nitrogen excretion on the protein free diet has been plotted against the nitrogen intake at equilibrium. The scatter points are closely bunched along a straight line which has the slope of mean K value 0.66. The dotted lines demarcate the standard deviation of the K values. Both the group of thirteen good experiments and the six more doubtful ones fall quicly well into the wedge within the boundaries of this standard deviation.

Fig. 2 also brings out the important corollary to Allison's equation that there was no tendency to constancy of nitrogen intake at equilibrium but that that value depended upon the endogenous nitrogen metabolism as represented by the nitrogen excretion on a protein free diet. The higher the latter the higher was the nitrogen intake required to produce equilibrium. In this group of patients four showed remarkably low nitrogen excretions in the control protein free periods (Patients 1, 9, 17 and 20). At first these low excretions were blamed on losses of specimens but careful examination failed to reveal any such technical carelessness. Besides the urine volumes in these cases were large the specific gravities low and the creatinine excretions generally constant. Furthermore, these four subjects showed K values very close to the average and the nitrogen balance curves were good approximations of straight lines. The low excretions were therefore probably genuine. The nitrogen intakes at equilibrium for these four patients were at unusually low levels of 42 to 62 mg per kilo, unit per day. On the other hand those patients with higher endogenous nitrogen excretions all showed higher intakes at equilibrium. None of this group had the unusually high excretions found by Co Tui and co workers⁹ in patients with burns or other conditions producing the so called catabolic assault. If there were such patients they likely would have shown much higher nitrogen intakes at equilibrium than seen in Fig. 1 if the K values were of the same order as the values found here.

The unusually high K value of 1.02 might represent a technical error especially in the determination of the endogenous excretion. An occasional subject when placed on the protein free high carbohydrate high fluid diet excreted relatively large quantities of nitrogen for several days before reaching a stable excretion. Thus with only a three or four day control period the patient might still not show the true endogenous excretion. If such a point was used as the pivotal point for drawing the straight line curve the slope would tend to be too steep making K too high. If however, this value was not due to error it

meant that in that particular patient the addition of protein to the diet spared endogenous metabolism. This phenomenon has been suggested by Allison in some of his balance studies with dogs.

Maximal Tolerance of the Hydrolysate—Of the nineteen subjects carried to the point of good positive balance, all but two finally received more than 100 Gm of the protein hydrolysate daily for at least three days. As much as 147 Gm were given daily to eight patients and 200 Gm to two patients for three days. No effort was made in these experiments to extend the injections beyond this period, and it is likely that some extension could have been made before the development of findings of intolerance such as nausea, vomiting, anorexia, or progressive thrombophlebitis. It may be significant that the greatest weight gains occurred in the patients who received as high as 200 Gm of amino acids daily. When the 10 per cent solution was used, the injection of 60 Gm usually required two to three hours for administration. Thus 180 Gm could be injected if need be, in six to nine hours and there would still be time for additional saline or glucose injection without infringement on the period of sleep.

The nitrogen balance curves in the region of high intake were not so steep as those in the region of negative or low positive balance. In fact, in several cases the curves became horizontal, indicating a ceiling of nitrogen retention. In one subject, however, a positive nitrogen balance of 13 Gm was achieved and in another, 10 grams. In the remaining patients the positive nitrogen balance increased only slowly with higher intakes, which posed the problem of whether the increased quantities injected produced enough additional retention of nitrogen to warrant the effort.

It has been maintained¹⁰ that parenterally injected amino acids so reduce the appetite as to cause a diminution of the oral intake of food. This phenomenon occurred in only six of the twenty patients studied here, as demonstrated by a slight drop in the caloric consumption as the quantity of amino acids injected was increased. Three of these patients were quite ill. In six other patients the total caloric intake actually increased slightly, that is, the patients requested and received a greater quantity of the high-carbohydrate drink. In the remaining eight patients the caloric intake remained constant throughout the study. In all cases the carbohydrate intake was nearly constant enough so as not to have any influence on the nitrogen requirement. There was therefore no confirmation of the idea that the injection of amino acids had a deleterious effect upon the overall appetite of the patient, even though immediately after an injection there was a temporary sense of fullness.

Effect Upon Circulating Proteins—The period of positive nitrogen balance was not extensive enough in these experiments to produce the expectation of a great gain in circulating proteins. The data shown in Table III indicate that though nearly all patients had marked hypoproteinemias there was little change for the better in the quantity of circulating proteins during the study. In fact in nine subjects there was a significant fall in the quantity of circulating proteins. In the five instances of rise of circulating proteins this rise was associated with an increase in plasma volume rather than an increase in serum protein concentration.

Table III also shows that the patients showed no significant weight change during the period of study. Twelve patients showed gains in weight up to 3 kilograms, but the remaining eight showed losses of equivalent quantities. Both the gains and losses were probably chiefly due to changes in body water content, for in all cases the caloric intake was little more than a maintenance one.

DISCUSSION

The data presented here offer unequivocal evidence that the lyophilized casein hydrolysate used in these studies on patients with chronic protein deficiency is a nutritionally and clinically adequate product. The material can be reconstituted easily with water, glucose solution, or physiologic saline to form a clear solution that is intravenously injectable without reaction. Positive nitrogen balance has been obtained in nineteen of the twenty patients studied. The quantities required for nitrogen equilibrium, though varying from an unusually low value of 42 mg per kilogram per day to the very high value of 349 mg, averaged 129 milligrams. This means that the average person is likely to obtain his daily nitrogen requirements with an injection of about 60 Gm, or one bottle of these amino acids.

But the adequacy of this protein preparation was determinable in this study by the method of minimal requirements for positive nitrogen balance only by virtue of the large number of balance experiments performed. A random selection of four or five patients might have given values for minimal requirements for equilibrium of the order of 50 mg per kilogram per day, or they might have averaged 200 milligrams. In the former case the parenterally injected amino acid mixture could have been regarded as superior to the best natural protein mixture given orally. If the latter values had been obtained the product would have been regarded as unsatisfactory. The range was found to be wide in spite of the choice of what was regarded as a homogenous group of patients with chronic protein deficiency and in spite of rigidly controlled regimens with adequate caloric intakes and with the same foods for all patients.

As in Allison's experiments with dogs, the nitrogen intake at equilibrium has been found to be dependent upon the nitrogen excretion on a protein-free diet. If the latter is small, equilibrium is established at a low intake. In general, this means that patients with long-standing protein deficiency require much less nitrogen for equilibrium than patients who have had recent acute losses, as has been found by Browne and co-workers.¹¹ Yet it was impossible to correlate endogenous nitrogen excretion in these chronically ill patients with the serum protein concentration or total circulating protein. Apparently the exact level of the circulating proteins is determined by many factors rather than merely by the degree of protein deficiency. Apparently, also, there is no easy clinical or laboratory method of anticipating the requirements for equilibrium other than nitrogen balance studies.

The finding of rectilinear curves in the region of negative and low positive balance in thirteen of the nineteen subjects offers proof of the applicability of the concepts of biologic value of proteins as expounded by Mitchell,¹² Allison

Terioine,¹³ and others to the study of a parenterally injected protein product in protein deficient human subjects. The relative constancy of the K value of these curves—the nitrogen balance index of Allison—in the face of variations in nitrogen intake requirements for equilibrium makes the determination of that value the better gauge of the adequacy of the protein derivative under study. The average value of 0.68 for the nineteen cases or 0.66 for the more reliable thirteen cases indicates a good protein. Allison found values of about 0.80 for orally administered casein and of 0.39 for a soybean protein. We have data¹⁴ which indicate that the protein hydrolysate used by us has a much higher biologic value when administered orally. Such a finding is to be expected in view of the fact that the higher plasma amino acid concentrations achieved with intravenous administration promote a greater destruction of amino acids and an increased urinary loss. Thus with oral administration of this product the K value might approach the value of 0.80.

Yet the use of the nitrogen balance index to characterize a protein as satisfactory as it is theoretically is not without its weaknesses in the study of protein deficient patients. In the first place it requires a long experiment of twenty or more days. In such protracted studies with an unattractive diet and with daily intravenous infusions it is difficult to maintain a constant level of cooperation of the patient and of his emotional reaction toward the dietary management. Besides, his clinical condition and therefore his protein requirements are likely to change during the course of the study. Second the accuracy of the curve depends primarily upon the establishment of the endogenous nitrogen excretion. This is not easy to determine accurately. When protein is removed from a calorically adequate diet the nitrogen excretion rapidly diminishes and is usually much lower on the third or fourth day than on the first or second. It has been necessary at times to discard the values of the first and second days. Smith¹⁵ found that the endogenous nitrogen excretion had not become stabilized even after twenty-four days of a nitrogen poor diet. Third the slope of the curve depends upon the accuracy of a number of points. The variable errors of the changing condition of the experiment, temperature variations, excretion losses, and analytic defects may combine to produce a succession of points for which no accurate rectilinear curve can be drawn. The number of experiments must be large to avoid the consequences of these inaccuracies.

Though these experiments were not designed for the study of the therapeutic value of parenterally administered amino acids, they offer some corroboration of our previous findings^{1, 2} that improvement of patients with long standing protein deficiency requires an intense and protracted program which is difficult to achieve with parenteral administration alone. Unless the biologic value of hydrolysates is markedly increased by the addition of individual essential amino acids the quantity of such amino acids that must be administered and the length of the program are too great to be clinically practicable.

The leveling of the curves of nitrogen balance on the high intakes indicates the approach of a ceiling of nitrogen retention. If the retention of each additional increment is no more than 10 or 20 per cent it becomes doubtful whether

the additional injections are worth the effort and the cost. Undoubtedly, however, there are many patients with severe protein deficiency who must be prepared for operation in as rapid a time as possible at whatever cost. In these instances the intravenous administration of large quantities of amino acids supplemented with whole blood and with as high an oral intake of food as possible might produce the desired results.

SUMMARY

Nitrogen balance studies were carried out in twenty patients with chronic protein deficiency. The experiments were performed with progressive increases in the nitrogen intake, the only significant source of nitrogen being a new parenterally injected lyophilized casein hydrolysate.

The lyophilized product could be injected without reaction in concentrations up to 10 per cent at reasonable speeds for periods up to twenty days.

Positive nitrogen balance was achieved in nineteen of the twenty subjects.

The nitrogen intake required for nitrogen equilibrium varied from 42 to 340 mg per kilogram per day. The average was 120 mg, with a standard deviation of 51 per cent. The values were directly proportional to the magnitude of the endogenous nitrogenous excretion.

In thirteen of the nineteen cases the curves of nitrogen balance were rectilinear in the region of negative and low positive nitrogen balance, in the remaining six, straight-line curves could be drawn but were not so well defined. In the region of high positive balance the curves tended to level off, indicating a ceiling of utilization. These findings are in corroboration of those of Allison for protein-starved dogs.

Allison's nitrogen balance index (K), which is the slope of the rectilinear curve of nitrogen balance, tended to be constant in all nineteen cases, averaging 0.68, with a standard deviation of 24 per cent. In the thirteen more precise cases, K averaged 0.66, with a standard deviation of 20 per cent. The nitrogen balance index was therefore found to be a more reliable indication of the quality of the protein under study than the nitrogen intake requirement for equilibrium. The latter can be used only when a large number of balance studies are carried out with a homogeneous group of subjects as in this study. By either criterion the results indicate that the lyophilized casein hydrolysate is the equivalent of a good protein.

The determination of the nitrogen balance index has the following disadvantages: (1) the requirement of a long, tedious, difficult balance study, (2) the inherent error of the estimation of endogenous nitrogen excretion, and (3) the difficulty in drawing an accurate straight-line curve.

Serum protein concentrations or total circulating protein levels were not appreciably increased during the balance studies. A much more intense and protracted regimen is required to alleviate severe chronic protein deficiency.

We wish to express our gratitude to Mrs. Irene Antonow Maxwell who as dietician prepared all menus, and to Miss Lorraine Schmelzle and Mrs. Jacqueline Schaefer for the chemical analyses.

injections appeared to be entirely innocuous but produced no detectable changes in symptoms or signs. None of our patients have yet shown any improvement attributable to cytochrome c.

From three of the patients and from the normal subject samples of blood were taken before, shortly after and twenty four hours after cytochrome c injections. The substance was not detected spectroscopically in the serum of these subjects except where blood samples were collected within thirty minutes after injecting single doses of 500 milligrams. Cytochrome c added to serum or water in vitro and reduced with hydrosulfite could not be detected with the hand spectroscope at concentrations of less than about 65 mg per cent. This concentration would correspond approximately to a dose of 325 mg in a total blood volume of 5 liters. One could not therefore expect to detect the cytochrome after smaller injections without more sensitive instruments. A pinkish color of the serum was observed in several samples but this was found to be due to hemolysis of red blood cells. The bands of oxyhemoglobin were readily seen spectroscopically but no bands of reduced cytochrome c could be seen on reduction with hydrosulfite. A solution of cytochrome c sufficiently strong to give an obvious pinkish color to serum or urine was found to contain about 20 mg per cent a concentration which is readily detectable with the hand spectroscope.

Samples of urine examined within thirty to ninety minutes after injection of doses less than 200 mg cytochrome c did not reveal the presence of this sub

stance When the doses injected were from 200 to 500 mg, the samples of urine, passed during the first few hours after injection, ranged from faint rose to deep copper in color, and the characteristic band of reduced cytochrome *c*, ranging from a faint thin line to a broad black band, was visible spectroscopically without the addition of reducing agent *

CONCLUSIONS

The pinkish color of serum observed by Proger and Dekaneas^{1, 2} after injections of cytochrome *c* may have been due to the presence of hemoglobin as a result of slight hemolysis Cytochrome *c* could be detected in serum by means of a hand spectroscope only immediately after large injections Considerably greater concentrations of the pigment are required to produce an obvious pink color

Injected cytochrome is rapidly removed from the plasma and considerable amounts are excreted in the urine

Intravenous injections of large amounts of cytochrome *c* produce no obvious effects While harmless, such injections were of no benefit in the few cases of neuromuscular disease studied

CARONAMIDE PLASMA CONCENTRATIONS, URINARY RECOVERIES, AND DOSAGE

WILLIAM P. BOGER, M.D.,* PHILADELPHIA, PA., AND A. KATHRINE MILLER, PH.D.,
ELIZABETH K. TILLSON, AND GRACE A. SHANER, GLENOLDEN, PA.

SINCE Caronamide† inhibits the enzyme transport system of the renal tubular epithelium by which penicillin is excreted,¹ the desirability of controlling dosage by accurate measurement of caronamide in the body fluids is obvious. When the initial studies with caronamide were carried out,² methods for determining caronamide plasma concentrations were not available. Dosage schedules were established by comparing penicillin dose response curves modified by caronamide with curves obtained on the same patients when penicillin was administered alone. On this basis it was found that from 9 to 12 Gm. of caronamide per day (15 to 20 Gm. every four hours) were sufficient to obtain a positive effect in some patients while others required 24 and even 32 Gm. per day (30 to 40 Gm. every three hours). The observation that different individuals required different dosages to bring about the same effect and the findings of others⁴ that age apparently influenced the size of the dose required to give the maximal result, clearly indicated the need for methods for determining caronamide in body fluids in order that dosage could be properly individualized.

It is the purpose of this paper to report the plasma concentrations following various doses of caronamide by the oral and parenteral routes of administration, some recoveries of caronamide in the urine and the correlation of simultaneously determined caronamide and penicillin plasma concentrations. The results of this work permit a clearer definition of the effective dose of caronamide.

Methods for Caronamide Determinations—

Method 1 This method,‡ requiring that a forty-eight hour alkaline dialysate of plasma be analyzed with the Beckman ultraviolet spectrophotometer proved to be more time consuming and less accurate than Method 3 and was abandoned as soon as the latter procedure became available. It was used, however, during the initial phases of this investigation, and results obtained thereby have been cited previously.⁵ Values obtained in this manner show substantial agreement with those obtained by Method 3 since both procedures measure the sum of caronamide and its modified forms.

Method 2 The Brodie method⁶ measures only free caronamide and not its conjugates. Acidification of urine or plasma precipitates caronamide which then is dissolved in chloroform. The chloroform solution is extracted with 0.1N sodium hydroxide solution and the resulting alkaline solution of caronamide is read in the Beckman ultraviolet spectrophotometer at 280 μ millimicrons.

response curves and it is observed that, even in this small group, there were marked differences in handling of the drug. The average values obtained from estimation of caronamide plasma concentrations of the six patients were 15.5 mg per 100 cc after one half hour and 8.0 mg per 100 cc of plasma at the end of three hours.

Repeated Oral Doses of Caronamide—Six patients, chosen at random in order that they might better represent the clinical conditions under which caronamide is likely to be administered, were given 3 Gm of the drug at three hour intervals for five doses. One hour after all but the first dose a blood specimen was drawn for caronamide determination. From the averaged results (Fig 2) it is clear that over the period of study there was a gradual rise in caronamide plasma concentration from 6.5 to 18.5 mg per 100 cc of plasma. All of these patients tolerated the drug well and no untoward symptoms were observed.

Fig

Since there appeared to be some tendency for the plasma concentration to rise gradually during a twelve hour period following initial administration of caronamide a similar study was conducted but observations were extended for a longer time. Five patients were given 15 Gm of caronamide every three hours and five patients received 30 Gm every three hours for one week. Several patients left the hospital before completion of the study and did not receive the drug for the full week. A plasma caronamide determination was made daily the blood specimen being drawn at approximately the same time each day from one to two hours following a dose of caronamide. Determinations on the plasma of Patient L N were estimated by Method 1 all the other results presented

CARONAMIDE PLASMA CONCENTRATIONS* FOLLOWING CONTINUOUS ORAL ADMINISTRATIONS

in Fig 3 were obtained by Method 3. Since Methods 1 and 3 both measure caronamide and its modified forms however, the results are considered together.

Despite marked individual differences in the handling of the drug, the difference between the plasma concentrations of patients on the two dosage schedules is clearly defined. The averaged data on the patients who received 3 Gm of caronamide every three hours show a rising concentration of the compound. As noted in Fig 3 the caronamide determinations were done on blood specimens drawn either one or two hours after a dose of caronamide. From dose response curves following a single dose of caronamide it has been observed that the one hour determinations are uniformly higher than those done two hours after medication. In consequence some of the tendency of the average figures in Fig 3 to rise over the seven day period may be more apparent than real. That this is probable is confirmed by observations that during more prolonged administration of caronamide increasing plasma concentrations did not occur.

Since Intravenous Dose of Caronamide—Although one of the chief advantages of caronamide is the fact that it is administered orally, some experiments with intravenous caronamide have been done.

Three patients were given a 75 per cent solution of sodium caronamide intravenously, 3 Gm being injected over a period varying from three to seven minutes. All of these patients experienced a mild sensation of warmth after 15 to 20 cc of the solution had been injected but otherwise there were no reactions. At the same time 200,000 units of penicillin were injected intravenously in order that it might be determined whether or not the plasma concentrations of caronamide were sufficient to produce an elevation of the penicillin plasma concentrations as compared with those obtained in a control period without caronamide. In all instances a marked elevation of the penicillin concentration was noted (particulars of these experiments will be reported in another publication), indicating that the concentrations of caronamide (Table I) were effective in inhibiting penicillin excretion. Observations were limited to an hour and forty minutes and during this period quantitative urine collections were made making possible the measurement of caronamide in the urine (Table I).

TABLE I CARONAMIDF PLASMA CONCENTRATIONS AND UPINAFY RECOVERIES FOLLOWING A SINGLE INTRAVENOUS DOSE OF CARONAMIDF

Average							1.08	35.9

All determinations done by Method (Brodie⁶)

Continuous Intravenous Infusion of Caronamide—Three patients in apparent good health and with normal renal function received 3 Gm of sodium caronamide intravenously as a priming dose (injection time three to five

minutes) and thereafter were infused with a solution containing sodium caronamide (Table II). The actual amounts of caronamide administered were 5.04, 4.95, and 4.3 Gm, respectively, to Patients I S, M F, and B B. The caronamide plasma concentrations that were noted following these doses are given in Table II. These determinations were made by employing Method 2.

TABLE II CARONAMIDE PLASMA CONCENTRATIONS FOLLOWING CONTINUOUS INTRAVENOUS ADMINISTRATION OF CARONAMIDE

PATIENT	AGE	CARONAMIDE		CARONAMIDE PLASMA CONCENTRATIONS* (MG/100 CC)			
		IRIMING DOSE (GM)	INFUSION (MG/KG/HR)	45 MIN	60 MIN	75 MIN	90 MIN

*All determinations done by Method 2 (Brodie's)

Recoveries of Caronamide After Oral and Intravenous Administration—Five patients (five of the patients listed in Fig. 3) were given caronamide every three hours for five days and on the sixth day, while the drug was still being administered, twenty-four hour urine specimens were collected. The total amount of caronamide in this collection was determined both gravimetrically and by Method 3. For the gravimetric determination caronamide is precipitated by acidifying the urine to a pH below 5.0 and thereafter the precipitate is washed, dried and weighed. By this method only caronamide is measured, since its modified forms remain in solution. Method 3 measured the modified forms of caronamide in solution and hence the values obtained are higher than those representing only caronamide (Table III).

Correlation of Caronamide Plasma Concentrations With Penicillin Plasma Concentrations—Dosage schedules for caronamide originally were set up without the benefit of caronamide plasma concentrations by determining the dose of caronamide that influenced favorably plasma concentrations of penicillin. When methods became available for determining caronamide in body fluids the dosage schedules previously established were re-evaluated.

Penicillin dose-response curves modified by caronamide were compared with penicillin dose-response curves obtained on the same patients when penicillin alone was administered. For each curve the dose of penicillin was the same and, when the curve modified by caronamide showed at least a twofold

CORRELATION OF CARONAMIDE AND PENICILLIN PLASMA CONCENTRATIONS

Fig 4 -- (Boger W P Caronamide A New Enhancing Agent for Penicillin in Conjunction With Penicillin Therapy Tr & Stud Coll Physl
 ians Philadelphia 13 104 144)

enhancement over the control curve, the result was regarded as satisfactory. On this basis, caronamide plasma concentrations were correlated with penicillin plasma concentrations (Fig 4).

From Fig 4 it is apparent that a caronamide plasma concentration of 1 mg per 100 cc approximates the critical value that determines the inhibition of the excretion of penicillin. The striking exception presented has been questioned because there was very real doubt that the patient received the prescribed amount of penicillin. The criteria used to determine the positive and negative effects of caronamide demand that the patient receive the same dose of penicillin in the control period and the caronamide treatment period. If this requirement is not fulfilled, a failure of caronamide may be implied where none exists.

DISCUSSION

It has not yet been determined whether or not the metabolic products of caronamide are physiologically active. For this reason there would appear to be some advantage in using a method for determining caronamide that measures both the drug itself and its conjugates. Methods 1 and 3 fulfill this requirement, but because of its simplicity Method 3 is preferred.

Method 2 measures caronamide alone and, when aliquots of the same specimen have been analyzed by Methods 2 and 3, the values of Method 2 have been roughly half of those obtained by Method 3. Despite this relationship it would be hazardous to depend on it for not all patients conjugate caronamide to the same degree. The urinary recoveries of caronamide in only a small group of patients (Table III) showed that patients such as H A and L N either do not conjugate the drug at all or do so to only a slight degree. Other patients excreted almost half the caronamide as a conjugate or metabolic product of caronamide. It is apparent, therefore, that values obtained by Method 2 will not bear a constant relationship to values obtained by Method 3. Application of the two methods in the study of a larger series of patients should give valuable information concerning the metabolism of caronamide.

It has been noted previously* that a reducing substance occasionally appears in the urine following caronamide administration. Nine of the ten patients presented in Fig 3 showed this reducing substance in the urine. The exact nature of this substance has not been determined, but it reduces Benedict's solution, is still present in specimens subjected to reasting, and gives a positive Bial's test. The last mentioned test generally is performed to determine the presence of a pentose. It is interesting to note that a reducing substance has been observed in the urine of persons treated with para-aminobenzoic acid⁹ and it is not unlikely that this reducing substance is the same as that observed following the administration of caronamide.

The demonstration that caronamide is effective in elevating penicillin plasma concentrations from two to seven times led to the conjectures whether the intervals between intramuscular injections of penicillin could be lengthened and whether caronamide might prolong the period of activity of a single intramuscular dose of penicillin in aqueous solution to equal the duration of action

of an injection of penicillin in oil and beeswax. The duration of action of a single dose of caronamide and the plasma concentration of caronamide required to inhibit penicillin excretion are intimately related to these questions.

At the beginning of investigations with caronamide clinical evaluation was handicapped by the inability to determine the compound in the plasma. Nevertheless it was found that a single 4 Gm dose of caronamide exerted an effect on penicillin plasma concentration for from five to seven hours. Later when methods for caronamide assay were developed it was found that a slightly larger single dose 4.5 Gm provided plasma concentrations between 8 and 15 mg per 100 cc (Method 1) for a period of three hours.

These plasma concentrations in man are in good agreement with the theoretic figure of 6 mg per 100 cc that is regarded as giving a good suppressive effect upon penicillin excretion in dogs.¹¹ Further the finding that the oral administration of a single 4 Gm dose of caronamide, that is approximately 50 mg per kilogram of body weight for an average adult weighing 70 kilograms (154 pounds) elevated plasma penicillin concentrations for from five to seven hours, confirms the finding in dogs that a single oral dose of 50 mg per kilogram that is 4 Gm for a dog weighing 20 kilograms decreased penicillin clearance for at least four hours.¹⁰

Since 4 Gm of caronamide as a single oral dose elevated penicillin plasma concentrations for from five to seven hours and a slightly larger dose (4.5 Gm) of sodium caronamide given orally resulted in a plasma concentration of 8 mg per 100 cc (Method 2) for only three hours it is suggested that even lower concentrations can partially inhibit penicillin excretion.

Reasoning from the foregoing, a dose of 4 Gm every four hours would maintain a plasma concentration of caronamide close to the one required definitely to inhibit penicillin excretion. Using this schedule of dosage it has already been shown⁴ that 100,000 units of penicillin in aqueous solution will sustain assayable penicillin levels in the plasma for as long as eight hours. It is doubtful whether caronamide doses can be spaced farther apart than every four hours since it is excreted rather rapidly and it seems desirable to maintain an adequate caronamide plasma concentration in order to assure at least a two fold increase in the level of penicillin.

It has not yet been determined whether by continued administration of caronamide it will be possible to prolong the effects of a single injection of aqueous penicillin to equal that of penicillin in oil and beeswax. However if assayable levels can be obtained for as long as eight hours after 100,000 units of aqueous penicillin when caronamide is given the likelihood is great that with larger doses of penicillin assayable levels can be extended to at least twelve hours. To prolong the effect of a single injection of penicillin and to circumvent the necessity of relying upon the patient to take additional medication single oral doses of 6 Gm of caronamide have been given in conjunction with 500,000 units of oral penicillin. This treatment has been applied to a group of patients with acute gonorrhea and the rate of cure has been 87 per cent.¹¹ Caronamide plasma concentrations following the administration of 6

Gm are not available at this time but, in consideration of the results obtained following a 4 Gm dose, it might be anticipated that 6 Gm of caronamide would produce a concentration that would influence penicillin plasma levels for at least six to ten hours. Apart from the inconvenience of swallowing the tablets, 6 Gm doses have been given without unfavorable reactions and investigation of large single doses of caronamide is indicated.

In Fig 3 the impression is given that a fixed dose of 3 Gm every three hours may cause an accumulation of the drug in the plasma. That this rising concentration may be more apparent than real has already been mentioned. It is worth while to point out, however, that we have had the opportunity of observing other patients not reported here who have taken 3 Gm every three hours for two and three weeks without showing either increasing plasma concentrations or symptoms of systemic toxicity. An occasional patient has complained of nausea and a few have vomited. It has been difficult to differentiate between simple nausea induced by the difficulty incident to swallowing a number of large tablets and that caused by drug toxicity. It has been interesting to observe that a number of these patients have been able to continue medication at the same dosage level when a suspension of caronamide replaced the tablets. However, several instances of vomiting probably due to drug toxicity have been encountered, and in two of these patients it has been shown that caronamide plasma concentrations were in excess of 70 mg per 100 cubic centimeters. This finding only emphasizes the desirability of controlling dosage by caronamide plasma determinations. It should be pointed out that caronamide concentrations of 45 mg per 100 cc and above generally are well tolerated (Figs 3 and 4).

In a previous publication,* on the basis of only two patients, it was suggested that 20 to 30 mg per 100 cc (Method 1) was the caronamide plasma concentration required to suppress the elimination of penicillin. On the basis of a larger experience and more reliable caronamide determinations, it appears that concentrations as low as 8 mg per 100 cc (Method 2) partially inhibit penicillin excretion and concentrations between 10 and 20 mg per 100 cc insure at least a twofold enhancement of penicillin plasma concentration (Fig 4). Concentrations between 20 and 40 mg per 100 cc are well tolerated and they approximate the plasma concentration of caronamide that provides optimal inhibition of penicillin excretion.

The dose that has most frequently fulfilled the requirement of maintaining for the entire time between doses of caronamide a plasma concentration that is adequate to inhibit penicillin excretion has been 3 Gm every three hours or 4 Gm every four hours. In a few instances this dose has failed to maintain the desired plasma concentrations and in others (Fig 3, Patients J C and J O, and Fig 4) 15 Gm every three hours have maintained the requisite level. Actually, the optimal dose of caronamide cannot be defined arbitrarily as a certain number of grams per day, the dosage necessary to maintain the plasma concentration at or above 15 mg per 100 cc varies from individual to individual and varies somewhat even in the same individual from day to day.

Diet, degree of hydration, fluid intake, fever, and disease influence to a marked degree the daily requirements of any particular patient. The avail

ability of a simple and reliable method for caronamide determination has established this clearly. Striking differences in individual requirements under conditions other than those just mentioned are probably a reflection of the patient's renal function. It appears that the more nearly normal renal function is the larger the dose of caronamide required to maintain a plasma concentration that will inhibit penicillin excretion. This generalization is compatible with the available clinical data. Children with normal renal function have been found to require daily doses equal to adult doses 24 Gm per day,¹ in order to obtain elevations of penicillin plasma concentration. Persons over 60 who, presumably on the basis of aging alone have some renal impairment require less caronamide to inhibit penicillin excretion than do younger individuals.⁴ Caronamide probably is excreted only by glomerular filtration and, consequently impairment of glomerular function will retain the drug in the circulation, thus making smaller doses more effective. Furthermore since the site of action of caronamide is the renal tubule any existing impairment of tubular function means that less drug will inhibit those tubules that are functioning normally. Thus if a patient to whom caronamide is administered has subclinical renal impairment, a relatively small dose of the drug will be required to maintain an optimal plasma concentration.

CONCLUSIONS

A caronamide plasma concentration of approximately 15 mg per 100 cc is required to inhibit the renal excretion of penicillin sufficiently to provide at least a twofold elevation of penicillin plasma concentration. A single oral dose of 4 Gm of caronamide will not maintain this concentration in the plasma but by reason of partial inhibition of the renal tubules will, nevertheless, influence penicillin excretion for from five to seven hours. Although 15 Gm every three hours in some patients provide this critical level (15 mg per 100 cc) in the plasma, 3 Gm every three hours or 4 Gm every four hours are required in the majority of patients with normal renal function. Caronamide plasma concentrations of 20 to 40 mg per 100 cc are well tolerated and probably represent the concentrations that maximally inhibit the tubular excretion of penicillin. There are marked individual differences in the metabolism of this compound but the average twenty-four hour recovery of free caronamide is 35.38 per cent and of caronamide and its metabolic products 47.26 per cent of the material injected. The availability of a simple and reliable method for caronamide determination permits individualization of caronamide dosage.

We wish to acknowledge our indebtedness to Dr. Harrison F. Flippin and Dr. William G. Leaman, Jr. for having granted permission to study patients on their services at the Philadelphia General Hospital, Philadelphia, Pa.

ISOLATION AND IDENTIFICATION OF INFLUENZA VIRUSES DURING THE EPIDEMIC OF DECEMBER 1945

MILDRED W. BARNES M.S. HIRNERT R. MOGAN M.D.,* AND
MAXWELL FINLAND M.D.
BOSTON, MASS.

THE ease with which influenza viruses can be isolated and identified from individuals ill with clinical influenza has varied considerably in different epidemics in different laboratories during the same epidemic and even in different patients studied in the same laboratory during the same outbreak. During the epidemic of influenza A which occurred in Boston in December 1943, and in sporadic cases that occurred during the ensuing weeks successful virus isolations were made quite readily from the throat washings of a small group of patients with clinical influenza and from the lungs of patients with fatal cases.¹ These isolations were accomplished by using unfiltered and untreated throat washings or lung suspensions either for intranasal mouse inoculation and passage or for inoculation and subsequent passage through the allantoic sac of developing chick embryos or by combinations of these methods. Bacterial contaminations were usually eliminated in the course of the mouse passages without resort to special methods, or by filtration after the virus had multiplied and become established either in the mouse lungs or in the allantoic fluid of the chick embryo. Similar methods were used successfully during the same epidemic by workers in Minnesota.^{2,3}

The same methods, except for the addition of adequate amounts of penicillin to suppress bacterial contaminations were entirely without success when used on materials collected from patients during and after the epidemic of influenza B that occurred in and around Boston in December 1945. After numerous attempts, influenza B viruses were eventually isolated from throat washings of a number of patients studied during this epidemic utilizing other routes of inoculation of embryonated eggs both with and without preliminary mouse passage.⁴ In view of the difficulties encountered and the different methods employed it may be of interest to present here some of the details of the experiences with the isolation of influenza viruses during this outbreak. The results have been reported elsewhere of the serologic studies made in cases and family contacts from a localized outbreak in a school in one of Boston's suburbs,⁴ in cases of uncomplicated respiratory infections⁵ and in patients with pneumonia⁶ seen at the Boston City Hospital during this epidemic.

Only three strains had been successfully established at the time that the report was made on the serologic studies in cases and family contacts from the school outbreak in Needham and only one of those strains was from a Needham case. Several other strains were subsequently isolated on one or more attempts both from children in Needham and from patients at the Boston City Hospital as detailed in this paper.

dissected out, pooled ground with sterile alundum and made up to a 10 to 20 per cent suspension with broth containing 10 per cent normal horse serum. This suspension was used for further egg passages when the allantoic fluid failed to agglutinate the chicken cells.

Allantoic Inoculations—For this purpose 10 to 11 day old embryonated eggs in groups of four to six were inoculated directly into the allantoic sac in the manner described by Hirst⁸. A hole was drilled on the side of the egg over the embryo but in an area where there were no large blood vessels. A second puncture was made in the shell over the air sac. An inoculum of 0.1 ml. was then injected with a 26 gauge needle one half inch long through the side opening directly into the allantoic sac. Both holes were then sealed with the colloidal iodine mixture. After two days of incubation at 35 or 37° C. depending on whether influenza B or A virus respectively was anticipated the allantoic fluid was harvested without previous chilling. The large blood vessels in the chorioallantois were ruptured and allowed to bleed into the allantoic cavity. The allantoic fluid containing the embryonic red cells was collected, pooled and concentrated according to the method of Francis and Salk¹⁰.

Mouse Inoculations—Mice in groups of six, each weighing 10 to 12 grams were inoculated intranasally under light ether anesthesia with 0.05 ml. of untreated throat washing. The mice were sacrificed on the third day, the lungs dissected out, and the presence or absence of lesions was noted. The lungs were then pooled, ground with sterile alundum and made up to approximately a 20 per cent suspension in 10 per cent horse serum broth. After slow centrifugation to remove coarse particles the supernatant fluid was removed and used for further passages.

Controls—Sterile horse serum broth and negative or unknown materials including throat washings and lungs from patients without clinical influenza were carried through all of the various egg and mouse procedures and yielded negative results in every instance. Care was taken not to work with established viruses on days when isolation procedures were being carried out.

Serologic Tests—The methods used for titrating the viruses and for the agglutination inhibition and complement fixation tests were similar to those used in previous studies reported from this epidemic⁴. Neutralization tests were carried out in chick embryos by the method of Hirst¹¹. The PR8 and Lee strains* have been maintained by allantoic passages in eggs. The BON strain^{12†} was not introduced into the laboratory until most of the strains from this epidemic had already been isolated.

Identification and differentiation of the viruses were carried out in part by the use of antisera prepared in rabbits. For this purpose albino rabbits weighing 2.5 to 3.5 kilograms were used, two for each strain of virus. Each rabbit was bled about 10 ml. from the marginal ear vein to obtain serum for controls in subsequent tests and was then injected intravenously with 0.1 ml. of concentrated active virus. The rabbits were again bled from the ear vein after ten to fourteen days and the serum obtained at this time together with

†Obtained from Dr. John F. Enders, Department of Bacteriology, Harvard Medical School.

the controls was heated at 60° C for twenty minutes and tested for inhibition of chicken cell agglutination by the homologous virus. If there was a satisfactory rise in titer, the rabbits were bled by cardiac puncture and the serum collected and stored in sealed tubes at -20° C.

RESULTS

Virus Isolations—Only fourteen throat washings obtained from patients with clinically typical cases of influenza were studied. Each of these washings, however, was used in from two to twenty-seven separate attempts to obtain virus by inoculation and passage utilizing various methods or combinations of methods. The source of the washings, the antibody titers of influenza A (PR8) and influenza B (Lee) in the serum of the patients from whom they were obtained, and the results of the various attempts to demonstrate the presence of virus in these washings are summarized in Table I.

Successful isolations were made on one or more attempts from eight of these fourteen throat washings. All of these eight washings were obtained between December 13 and 21 from patients who developed significant rises in titer of antibodies for influenza B and not for influenza A.* The six which failed to yield any virus include all three of the washings that were obtained after the middle of January from patients who developed a rise in antibodies for the PR8 strain of influenza A and not for the Lee strain nor for any of the recently isolated strains of influenza B. Interestingly enough, two of the other three failures were with the latest washings obtained from patients with serologic evidence of influenza B. The serums of two of these patients, W D and J C, showed, in addition fourfold or greater rises in antibodies to three strains (MB VF, and WC) of influenza B that were isolated from this epidemic. The washings from J C, however, were not carried through the usual blind passages in eggs. Of all the six washings which failed to yield a virus, only the one from W D was obtained on the third day of illness, the others were collected on the first or second day.

With the washings that yielded viruses, the same methods were not always equally successful. There were not enough observations made with each method or combination of methods to permit definite comparisons. The available data nevertheless seem to warrant some deductions as to the relative efficacy of the different methods. The amniotic route of inoculation was definitely the most successful for the direct isolation of the viruses in eggs. In no instance could virus be established if washings were inoculated initially by the allantoic route. Inoculation directly into the embryo was not used as often as the other methods and was somewhat more cumbersome but it seemed to yield results similar to those obtained by amniotic sac inoculations.

Mouse inoculation and passage was not successful alone in establishing any of the viruses. Indeed when typical lesions were present in the lungs of mice inoculated with the original washings the lesions usually became progressively

*Since this paper was submitted successful isolations of influenza B virus were made from stored throat washings of Case 16 (J C) on three separate occasions. The virus was first recognized in Am in one instance in M₁A1 in a second and in M₁Am in the third. It was maintained through Am₁A1 the second through M₁A1 and the third through M₁Am₁A1.

less marked or were not seen grossly after further mouse passages. On the other hand, one or more passages through mice seemed to result in a sufficient increase in concentration of virus to permit a better yield and more rapid establishment of the virus after subsequent amniotic passage in eggs. Preliminary mouse passage also permitted the establishment of the virus directly in the allantoic sac of the chick embryo on several occasions without preliminary amniotic passage.

A few details of interest and some of the difficulties encountered in the course of these isolations may be mentioned briefly. There seemed to be considerable fluctuations in the amount, or possibly the virulence, of the viruses during the course of the amniotic passages and before they were stabilized by subsequent allantoic passages. It was difficult in the early passages, for example to judge from the hemagglutination titers the dilution of amniotic or allantoic fluid to use for subsequent passage either by the amniotic or allantoic routes. It was necessary, therefore, to use two, three, and sometimes four different dilutions of fluid for injections by both the amniotic and allantoic routes in order to assure a good virus yield and to avoid the loss of the virus in passage. Furthermore, the detection of virus in allantoic fluid, even in moderate or high titer did not always assure subsequent successful allantoic passage even when several dilutions of virus were used. Eventually, however, it was possible to passage some of the viruses consistently by the allantoic route, although not all of the strains were carried through to that stage.

Storage of the throat washings or of passage materials in the carbon dioxide icebox did not seem to affect the viruses appreciably, at least as judged by the facility with which isolations were subsequently made from these materials. Viruses were isolated from original washings and first egg passage materials by two individuals working independently, as long as fifteen to eighteen months after they were originally stored.

One point of particular interest was the progressive decline in titer of virus in the amniotic fluid with a concomitant increase in titer of the virus in the allantoic fluid during the course of incubation of the amniotic passages. Three striking examples of this phenomenon are shown in Table II.

TABLE II VIRUS TITERS IN AMNIOTIC AND ALLANTOIC FLUIDS AT VARIOUS INTERVALS AFTER AMNIOTIC INOCULATION

Identification and Differentiation of Strains—

Human Convalescent Sera In the course of the serologic studies of the cases from the school outbreak in Needham,⁴ some evidence was obtained which suggested that there were antigenic differences among the strains of influenza virus isolated in this epidemic although the strains were readily identified as influenza B. Most of the patients from Needham who had clinically typical influenza showed a characteristic rise in antibody titer in the convalescent sera with the Lee strain of influenza B as well as with three recently isolated strains but not with the PR8 strain of influenza A virus.

There were three patients in that group however who failed to show a rise in antibodies by the agglutinin inhibition test with the Lee strain and with one of the recently isolated strains but did show a rise with the other two epidemic strains that were used. In two of these three patients similar results were obtained with the complement fixation test, but in the third patient the complement fixation test showed similar rises in titer with all of these four strains of influenza B virus. The serologic findings in these three children and in the three patients from whom the viruses were isolated are shown in Table III.

J M	11	11	10	44	--	--	10	32	10	40	12	48

Patients M B, J H, R V, and J M were 1, 14, 11, and 1 years old respectively and were from Needham. W C and M F were adult workers at the Boston City Hospital. Titers with homologous virus are shown in bold type.

On the basis of the meager evidence obtained from the serologic response in the three Needham patients, the strain MB that was isolated from another case in Needham appeared to be antigenically closely related to the Lee strain. On the other hand strains MF and WC which were isolated from individuals in Boston who had not been exposed to patients from Needham, differed from these two strains and were closely related to the Australian BON strain¹ of

influenza B. It is interesting to note that these differences in antigenic response to the different strains of virus were obtained in school children ranging in age from 11 to 17 years. No such specific differences in antibody response were noted in the convalescent sera of the adult patients from the Boston City Hospital.

The fact that only the convalescent sera from some of the school children showed these specific differences may be due to their having had fewer previous exposures to influenza antigens, particularly to those of type B strains. This may have permitted their antibody response to express greater specificity when compared with the antibody reaction of older patients.

Immune Rabbit Sera. The titers of agglutinin-inhibiting antibodies in the rabbit sera prepared against these various strains are shown in Table IV. The results of these tests corroborate the findings in the human convalescent sera. They show that the MB strain is indistinguishable from the Lee strain of influenza B while strains WC and MF are identical with each other and are easily differentiated by this method from the first two viruses. The WC and MF strains furthermore, appear to be closely related to the BON strain. All of these strains were easily differentiated from the PRS strain of influenza A virus.

The titers of antibodies for the homologous virus in the rabbit sera obtained at the time of the final bleeding are also expressed in Table IV as fold rises. This was done because the rabbits used for immunization with the MF strain had a high titer (1:128) of hemagglutinin-inhibiting activity before the immunization. The subsequent fourfold increase in antibody titer in these rabbits was less than in those which were immunized with the other strains and in which the control titers were lower. The anti-MF serum was less active than the other rabbit antisera and the difference was even more marked in the results obtained in the virus neutralization tests with these sera.

TABLE IV. CHICKEN CELL HEMAGGLUTINATION INHIBITION TITERS OF ANTISERA PREPARED IN RABBITS AGAINST SPECIFIC STRAINS OF INFLUENZA VIRUS

VIRUS	TITER OF HOMOLOGOUS RABBIT SERA AT TIME OF FINAL BLEEDING			TITERS OF IMMUNE RABBIT SERA TESTED SIMULTANEOUSLY AT A LATER DATE					
	CONTROL	IMMUNE	FOLD RISE	PRS	LEE	BON	WC	MF	MB

Lee	1	1024	256	8	64	8	16	16	64
BON	32	256	8	8	32	64	32	32	32
WC	16	256	16	4	16	16	128	64	16
MF	128	512	4	4	16	32	64	64	16
MB	16	256	16	16	128	8	16	16	128

Titers with homologous virus are in bold type

The results of the virus neutralization tests performed on embryonated eggs are shown in Table V. These tests appear to be more sensitive and more specific and, therefore, give a more accurate measure of the antigenic differences. In these tests the control or normal rabbit sera showed no neutralizing activity with any of the viruses. The results otherwise confirm the close antigenic relationships of strains MB and Lee and their differences from strains WC, MF, and BON which are closely related to each other. There are also minor but

suggestive antigenic differences between WC on the one hand and MF and BON on the other. These latter differences however may be due in part to the fact that the neutralizing titer of the antiserum prepared with the WC strain was appreciably higher than that of the MF and BON antisera.

*Titer expressed as the reciprocal of the dilution of serum which inhibits growth in 10 per cent of embryos inoculated with 300 ID₅₀ (50 per cent infecting doses)

Hemagglutination of Horse Cells The ability of all of these strains of virus to agglutinate horse red blood cells was tested in order to detect any possible difference in activity similar to that found for some strains by Burnet.¹¹ There were some suggestive differences but these were not marked nor were they observed consistently in repeated tests.

Attempts to Demonstrate a Receptor Gradient Experiments were also performed to determine whether any possible differences in these viruses could be determined by the receptor gradient analysis as described by Burnet and co-workers.¹⁴ Each of the viruses was used to agglutinate chicken red blood cells. The viruses were then eluted from the red cells. The cells from which each of the viruses was eluted were then used for agglutination with all the viruses. No appreciable differences were noted in the effect on the red cells of any of the strains of influenza B virus that were tested in this manner.

SUMMARY AND CONCLUSIONS

Details of the isolation and identification of influenza viruses from throat washings obtained from patients with clinical influenza in and around Boston during the epidemic of December, 1945 have been presented.

Strains of influenza B virus were isolated only during the height of the epidemic from patients whose convalescent sera showed a rise in antibodies for influenza B and not for influenza A.

The amniotic route of inoculation of chick embryos was the most successful for the primary isolation of these viruses. Preliminary mouse passage was sometimes helpful in establishing the virus more rapidly in the embryonated eggs.

Evidence was presented which indicated that at least two antigenically distinct strains of influenza B were active in this epidemic.

HISTAMINE ANTAGONISTS

A NEW ANTIHISTAMINIC DRUG 2 [α (2 DIMETHYLAMINOETHOXY) α METHYL BENZYL] PYRIDINE SUCCINATE (DECAPRYN SUCCINATE) EXPERIMENTAL AND CLINICAL RESULTS

SAMUEL M. FEINBERG, M.D., AND THEODORE B. BERNSTEIN, M.D.
CHICAGO, ILL.

RAPID developments in the field of antihistaminic drugs have led to the synthesis of another new compound which, according to our experimental and clinical experiences, is an effective antihistaminic and antiallergic agent. This substance is 2 [α (2 dimethylaminoethoxy) α methylbenzyl] pyridine succinate, which the manufacturer calls Decapryn succinate.*

Laboratory studies by Brown and Weiner¹ have demonstrated that decapryn succinate is an antihistaminic agent with comparatively high potency and low acute and chronic toxicity. Minimal doses necessary to antagonize $\frac{1}{4}$ to 7 LD₁₀₀ of histamine were reported to be less than 0.5 mg per kilogram intravenously and subcutaneously and 10 mg per kilogram orally, lethal doses by these routes were sixty four or more times the effective doses. Protective action in these tests was of long duration, as evidenced by the fact that seven lethal doses of histamine were antagonized ten hours after the oral administration of 80 mg per kilogram of the antihistaminic agent.

Decapryn succinate effectively antagonized the depressor response in cats and the pressor response in rabbits resulting from histamine. It was found to have practically no topical anesthetic action on rabbit cornea but alkalinization of solutions liberated the base and resulted in strong local anesthetic action. The succinate also produced strong anesthetic action of long duration when injected with epinephrine. It prevented anaphylactic death in guinea pigs passively sensitized to horse serum, it antagonized the massive edema producing effects of intraperitoneally administered egg white in rats, and both oral and topical applications antagonized in some measure the contact dermatitis induced by chemical antigens.

These data indicated to us that decapryn had properties warranting further experimental and clinical study.

From the Department of Internal Medicine, Division of Allergy and the Allergy Research Laboratory, Northwestern University Medical School.

Part of the experimental work was supported by a grant from the National Health Institute of the United States Public Health Service.

Received for publication Nov. 28, 1944.

Supplied by the Wm. S. Merrell Company, Cincinnati, Ohio.

EXPERIMENTAL INVESTIGATIONS

Decapryn succinate produces very little surface anesthesia of mucous membranes. Unlike most of the other antihistamine drugs, a few crystals on the tongue did not produce noticeable numbness. One or two per cent solutions in the rabbit's eye did not abolish the sensitivity of the cornea. However, the intradermal injection of a solution into the guinea pig indicated that it is a local anesthetic about equal in potency to novocaine.

Intravenous Histamine—The 1 MLD 100 of histamine (0.4 mg of histamine base per kilogram) given intravenously to guinea pigs resulted in a survival of ten out of ten animals when an intraperitoneal injection of 1 mg of decapryn succinate per kilogram was administered twenty minutes previously. When 0.1 mg per kilogram of the drug was injected, two of five animals died after 1 MLD 100 of histamine.

Aerosols in the Prevention of Histamine Bronchospasm—We have found that aerosols of the antihistamine drugs were effective in the prevention of dyspnea from aerosolized histamine to which the guinea pigs were subsequently exposed. Ten animals were selected which responded to our histamine aerosol (0.5 mg per cubic centimeter at 5 pounds pressure) with the production of labored breathing in one-half to three minutes. These same animals were subjected on different days to the antihistamine drug, usually in strengths of 2, 1, $\frac{1}{2}$, and $\frac{1}{4}$ per cent for a five-minute period. After fifteen minutes the animals were exposed to the histamine aerosol and the time required to produce dyspnea was noted. If no dyspnea occurred after ten minutes the animals were removed. Periodically the animals were tested for changes in histamine tolerance and, if changes were noted, were replaced with other animals.

TABLE I. EFFECT OF DIFFERING CONCENTRATIONS OF AEROSOLS ON GUINEA PIGS TOLERATING HISTAMINE AEROSOLS (TEN ANIMALS WITH A NORMAL HISTAMINE TOLERANCE OF ONE HALF TO THREE MINUTES)

The essential results with decapryn succinate in comparison with Pyri benzamine and two other drugs are briefly reported in Table I. It may be seen that while decapryn succinate as an aerosol is not so effective as some anti histaminic drugs, it is more effective than others.

Anaphylaxis—Some degree of protection against anaphylaxis was evidenced by the fact that of nine animals passively sensitized with antiegg serum and challenged with 0.5 cc of 10 per cent egg white intracardially only one died of anaphylaxis when an intraperitoneal injection of 3 mg of decapryn succinate per kilogram was used thirty minutes previously. With a 1 mg per kilogram dose the protection was practically nil. The control group showed a mortality of 85 per cent.

Inhibition of Local Histamine Skin Response in Man—Early in our experience with the antihistaminic drugs we demonstrated that when applied locally to skin scratches these substances were highly effective in inhibiting the wheal and flare of histamine from subsequent application. Since it is reasonable to suppose that the histamine skin response in man comes much closer than animal assays to simulation of the mechanism of the allergic phenomena which we attempt to ameliorate it was hoped that quantitative studies of the inhibiting action of this histamine reaction might be a valuable means of obtaining a preliminary assay of the drug in question. At this point we shall not go into detail concerning the various techniques and the modifications which we employed nor

Fig 1—Quantitative inhibition of histamine reaction. Suitability and sensitivity of the particular subject are determined by preliminary titration of histamine dilutions applied to the site of scratches on the back (column at left). Dilution of antihistaminic drugs—A Pyribenzamine N (pyridyl N benzyl N dimethylethylenediamine hydrochloride) B Decapryn succinate C (1-dimethylaminoethoxy) (4-methylbenzyl) pyridine succinate D Chlorothal N (dimethyl N (pyridyl) N (1-chloro-2-phenyl) ethyl n-diamine hydrochloride) E Hetriamine N (dimethyl N benzyl N (4-pyrrolidyl) ethylenediamine hydrochloride)—are applied to several rows of scratches on the same subject at the same dilution. The drugs are washed off ten minutes later and 1 drop of a selected concentration of histamine (in this case 1:4000) is applied to each of the scratches. The comparative inhibitive effect of the drug gives a good indication of its antiallergic efficacy. The procedure is repeated on a number of subjects. Other modifications of the technique based on the same concept are being used.

discuss our general data with respect to other drugs. We shall outline here one method which can be used to obtain data and also the results obtained with decapryn succinate.

The suitability and the sensitivity of the subject are determined by performing tests with serial dilutions of histamine on scratches on the back. The dilutions commonly employed range from 1/4,000 to 1/128,000 in terms of histamine base. The concentration which is twice that of the lowest giving the maximum flare is usually employed in the inhibition experiments. Several series of scratches are made on the back. On each series of scratches drops of an antihistaminic substance of serial dilutions are placed, the range varying from 2 per cent to 1/32 per cent*. After ten minutes the antihistaminic solutions are washed off and the selected concentration of histamine is applied to the pretreated sites. Inhibition of the histamine reaction is shown in the sites which had the more concentrated antihistaminics, while the sites which had the weak solution may react. The point at which a histamine reaction fails to be inhibited gives an idea of the antihistaminic and probably the antiallergic potency of the drug. The experiment is, of course, repeated on a number of subjects.

Fig. 1 gives an idea of a representative result and indicates that decapryn succinate is effective in the inhibition of histamine reactions.

CLINICAL FINDINGS

General Procedure—After some of the experimental work had been done, the drug was administered cautiously to several subjects. When no particular toxic effects were noted decapryn succinate began to be used for the symptomatic relief of allergy. The patient was given the drug in the form of capsules or tablets and instructed to use small doses at first and only when needed. In a few instances the medication was prescribed to be taken regularly two to four times daily. In most instances the patient was seen twice weekly, when his condition was evaluated by questioning and observation and judged in terms of pollen counts, weather changes, and similar factors. Whenever feasible the subject was asked to compare the action of this drug against one or more others at various times. The results were regarded as satisfactory if relief was consistently obtained, although not necessarily every time. If relief was very slight or questionable or not obtained most of the time the result was recorded as "no improvement."

Hay Fever and Nonseasonal Allergic Rhinitis—The seasonal group comprised eighty-one patients, observed during the 1947 season, having seasonal hay fever either due to the pollens of grasses or ragweed or to fungus spores. Subjects with hay fever due to ragweed predominated. While some of the patients to whom this drug was given were new or untreated, the majority had received previously varying amounts of desensitizing injections. Satisfactory relief was obtained in sixty-two of the persons with hay fever (76 per cent).

*More recently we have found the following factors more suitable: histamine range of 1/8,000 to 1/512,000 for control titration; concentration of histamine for inhibition either the first effective flare or one which is one-half size of maximal; and antihistaminic concentration ranging from 1/800 to 1/204,800.

The relief was, of course, only temporary. The duration of action is difficult to determine in hay fever, our impression however is that there was a tendency to longer action than found with other antihistaminic drugs.

In the nonseasonal vasomotor rhinitis, nineteen of thirty-four patients obtained satisfactory improvement. In both the seasonal and nonseasonal types of rhinitis the hyperesthetic symptom of sneezing was more often relieved than the nasal bloating. The intumescence of the turbinates, so common a manifestation of the latter part of the hay fever season was resistant to this drug as well as to other antihistaminic drugs.

Other Allergic Manifestations—No appreciable relief could be observed in any of twenty-seven patients with asthma. Most of the patients with asthma in this group were associated with hay fever. This fact cannot be overstressed. In hay fever asthma, the hay fever may be effectively relieved whereas the asthma is not. Since desensitization treatment is highly effective in the prevention of such asthma, it is obvious that antihistaminic therapy should not be depended upon in such cases. Two patients of seven had relief of allergic cough.

The itching and some of the swelling of urticaria and angioneurotic edema were relieved in six patients of nine treated. Six patients with chronic atopic dermatitis received decapryl succinate; four had appreciable relief of itching. Dermographism was effectively relieved in five of six patients. Two patients with headache of possible allergic origin failed to obtain benefit.

Doses—The doses administered varied from 12.5 to 50 milligrams. We found no one who failed to tolerate as little as 12.5 mg. and doses larger than 50 mg. usually either were not needed or were not tolerated well. It is true that some patients who failed to obtain relief from 50 mg. doses might have obtained benefit from larger amounts. It is also true that some of those who obtained results from 25 mg. doses without toxic effects may have been relieved by smaller doses. This is a phase of therapy which will have to be decided in the future. However it is well to emphasize here that decapryl succinate has in some patients a highly soporific action and large doses should not be prescribed to an individual without previous trial of smaller doses.

Of the sixty-two patients with hay fever who obtained relief thirty did so with 25 mg. doses and 3 with 12.5 milligrams.

Side Actions—Of one hundred eighteen patients side actions to the drug were observed in thirty-nine (34 per cent). Of this number sedation or sleepiness was seen in thirty-six. In some patients this sedative effect was very pronounced. In one instance sleepiness and a feeling of numbness lasted from twenty-four to thirty-six hours. Usually, however, the sedative effect did not prevent the use of the drug. Nervousness was noted in four patients and vertigo also in four. Two patients complained of headache, one of epigastric pain and another of an itching rash. No serious or remote toxic effects have been noted after six months' use of the drug.

TABLE VI ANTISPASMODIC ACTIVITY OF 2 PS, ATROPINE, AND PAPAVERINE ON ISOLATED RABBIT JEJUNUM

COMPOUND	MINIMAL EFFECTIVE CONCENTRATION		
	NORMAL INTESTINE	VS ACETYLCHOLINE (1 1,000,000) SPASM	VS BaCl (1 10,000) SPASM
2 PS	1 50,000	1 50,000	1 100,000
Atropine	1 10,000,000	1 80,000,000	1 200,000
Papaverine	1 150,000	1 100,000	1 150,000

Antiacetylcholine action was further studied in cats anesthetized with Amytal Sodium. Intestinal activity was recorded by a tambour connected to a balloon inserted into the jejunum, with a water manometer in the system to regulate intestinal pressure. Blood pressure was recorded in the usual manner from the carotid artery. The intestinal responses were standardized by repeated intravenous injections of 0.01 mg of acetylcholine per kilogram, and no preparation was used unless identical consecutive responses were obtained. 2 PS was then injected intravenously and was followed by the standard acetylcholine injections at two- to four-minute intervals. 2-PS in a dose of 4 mg per kilogram antagonized acetylcholine action on the intestine by approximately 50 per cent. Twice this dose produced a slightly greater inhibition. The effect of 2-PS on the blood pressure response to acetylcholine was not evaluated since in these experiments the acetylcholine doses employed were far above minimal doses required for maximal responses in the blood pressure.

Blood Pressure and Respiration—Intravenous injections of 2 PS in cats anesthetized with Amytal Sodium, given at a rate of 2 mg per minute, produced a slight temporary pressor effect with doses of 2 mg per kilogram and either a slight pressor or depressor effect with doses of 4 and 8 mg per kilogram. A rapid rate of injection of 20 mg per minute produced a transient fall in blood pressure with doses of 8 mg per kilogram and a slight pressor or depressor response with 2 and 4 mg per kilogram.

Respiration generally was increased temporarily in both rate and depth with doses of 4 and 8 mg per kilogram regardless of the rate of injection. Smaller doses had no appreciable effect.

Irritation—2-PS produced no signs of irritation or tissue damage following mg either one minute instillation in rabbits' eyes of solutions up to 4 per cent or the injection of 1 per cent solution subcutaneously in guinea pigs and intramuscularly in rats. Subcutaneous and intramuscular injections of 3½ and 4 per cent solutions in rats produced irritation and some necrosis.

SUMMARY

Experiments in laboratory animals demonstrate that 2-[α -(2-dimethylaminoethoxy)- α -methylbenzyl]-pyridine succinate (2-PS) has a comparatively low toxicity and has potent antagonistic action to the effects of histamine on various tissues.

It suppresses bronchial constriction resulting from intravenous injection of histamine in guinea pigs. Following intravenous administration, it antagonizes in average of up to 200 lethal doses of histamine and prevents death.

in some animals from 320 lethal doses. A high degree of antagonistic action also follows subcutaneous and oral administrations in guinea pigs, and the protective action is of long duration.

2 PS effectively antagonizes arteriolar constriction and pressor effects of histamine in rabbits and it also antagonizes the depressor action of histamine in cats. Effective doses of histamine for these two vascular effects are increased roughly fifteen to thirty fold.

Cutaneous effects of histamine, as measured by the whealing reaction in rabbits, are antagonized. The increased capillary permeability demonstrated by localization of intravenously injected dye is prevented for eight or more hours following a single dose of 2 PS orally.

2 PS has considerable local anesthetic activity and it is weakly antagonistic to acetylcholine.

THE EFFECTS OF ADRENALIN IN NORMAL AND HYPERTENSIVE PATIENTS IN RELATION TO THE MECHANISM OF SUSTAINED PRESSURE ELEVATIONS

D M GRELN, M D, A DEAN JOHNSON, M D, ALLEN LOBB, M D, AND
GEORGE CUSICK M D
SEATTLE, WASH

THE enigma of hypertension is not alone that the pressure rises but also that it fails to be restored to its former level. Many internal and external agents are capable of elevating the human blood pressure. Ordinarily homeostatic mechanisms induce a reversion to normal. The existence of sustained hypertension implies that the restorative mechanisms are either ineffective or in restraint.

One of the most important of these mechanisms is constituted by the modulator nerves, the interruption of which can produce a prolonged elevation in pressure. Investigations of the effect of carotid sinus stimulation by Weiss and Baker,¹ Moore and Allen,² and Thomas³ have demonstrated that this mechanism is capable of greater depressor activity in the hypertensive person than in the normal person, indicating that sustained hypertension is not due to a reduction in the effectiveness of moderator action on peripheral structures. This capacity for vascular relaxation has been confirmed by a number of independent methods. Allen and co-workers⁴ and Gregory and Levin⁵ have reported that the pressure of hypertensive patients is reduced to values approaching normal by spinal anesthesia. Chasis and associates⁶ induced prolonged remissions by utilizing the vasodilator action of parenteral pyrogens. More recently, the tetracetyl ammonium ion like carotid sinus stimulation, has been shown by Berry and co-workers⁷ to cause a pressure fall which is of greatest intensity in subjects with elevated pressure.

The concept of relatively ineffective homeostatic mechanisms is suggested by tests designed to show that hypertensive persons react excessively to pressor stimuli. Perhaps best known is the cold pressor test of Hines and Brown,⁸ the use of which has been extended to single out prehypertensive individuals. However, exaggerated responses could not be demonstrated consistently in hypertensive patients by Pickering and Kissin⁹ and were found absent in hypertension due to chronic renal disease by Miller and Bruger¹⁰ and Alam and Smirk.¹¹ The use of the test to predict the subsequent occurrence of hypertension in pregnancy was attempted without success by Chesley and Chesley¹² and Wellen.¹³ An increased incidence of hyperreaction with age was demonstrated for both normal and hypertensive subjects by Russek and Zolman,¹⁴ while marked variability of response on repetition was reported by Goldring and Chasis in studies conducted on the same subjects over a period of years.¹⁵ The sum

Received for publication Dec 12 1947

of these investigations indicates that a general relation between the level of blood pressure and the intensity of the cold pressor response has not been demonstrated.

The average pressor response to breath holding was reported by Ayman and Goldshine¹⁶ to be two to four times greater in hypertensive persons than in normal individuals. However 20 per cent of their normotensive subjects were hyperreflexors. Feldt and Wenstrand¹ compared the reactions to breath holding and cold in the same individuals. Correlation was absent in more than 25 per cent of the group.

The interpretation of the cold pressor breath holding and similar tests is complicated by the reflex nature of their action. As a consequence variations in the pattern of response cannot be ascribed primarily to differences in the capacity of the cardiovascular apparatus to compensate for a fixed stimulus but may be due rather to alterations in the intensity and duration of the discharge induced by the various types of reflex pressor stimuli.

The present study was designed to determine whether the pattern of response of the hypertensive person differed significantly from that of the normal individual when evoked by a pressor stimulus which bypassed the initial reflex arc. Adrenalin was chosen as the stimulus not only for its direct action on heart and vessels but also because of its rapid inactivation. It was decided to give the drug by continuous infusion at various rates since this type of administration allows better dosage control, avoids differences due to rate of absorption and local sensory stimulation and facilitates equilibrium between the pressor actions of the drug and the depressor mechanisms of the subject.

Previous investigations of the action of adrenalin as modified by the initial pressure have been productive of varied results. The subcutaneous injection of 1 mg. was reported by Clough¹⁷ to produce a greater incidence of excessive reaction in hypertensive subjects. However these reactions did not seem to be related to the type, extent or duration of the pressure elevation. On the contrary intravenous administration of single doses by Hongrighy¹⁸ produced responses of the same magnitude in normal dogs as in those whose pressures had been significantly lowered by adrenalectomy. Continuous infusion of adrenalin at the rate of 2 mg. per hour was reported by Koehler and co-workers²⁰ to produce a rise in systolic pressure but a fall in diastolic pressure in both normal and hypertensive persons. Both the systolic rise and the postinfusion fall in pressure were said to be greater in subjects with elevated pressure.

EXPERIMENTAL METHOD

A total of eighty studies was carried out on thirty nine male and twelve female subjects whose blood pressures ranged from 90 to 246 mm. Hg. systolic and from 55 to 126 mm. diastolic. The age distribution is detailed in Table I.

Initial blood pressure and pulse values were established during the administration of saline through a three way stopcock connected to a calibrated drip apparatus. The stopcock was turned to permit infusion of the adrenalin solution from a flask suspended 200 cm. above the individual.

Pulse and blood pressure values were determined every three to five minutes during the course of the infusion every one minute for the first fifteen minutes after the infusion and at lengthening intervals throughout the next twelve hours.

TABLE I AGE DISTRIBUTION OF ADRENALIN INFUSION SUBJECTS

AGE (YR.)	NUMBER OF SUBJECTS
30-39	6
40-49	15
50-59	7
60-69	12
70-79	11

Samples of blood were drawn for determination of the hematocrit value before infusion, again when the initial dose had produced its maximum effect, and finally at the point of minimum blood pressure following cessation of the infusion.

The adrenalin solution was made up immediately before use by diluting a standard U S P stock solution with isotonic saline to a final concentration of 10 mg per cent. A fresh bottle of the stock solution was used for each six patients. Normotensive and hypertensive patients were treated alternately. From time to time different stock solutions were checked against one another on the same patient. No significant variations in activity were noted.

The earlier subjects in the series were given adrenalin at an initial rate of 0.31 to 0.30 μ g per kilogram per minute. Later the initial rate was lowered to a value lying between 0.11 and 0.30 μ g per kilogram per minute since unpleasant side effects were encountered occasionally with the higher dosage.

When the starting level had produced its maximum effect on blood pressure, the rate of administration was increased in steps of 0.20 μ g per kilogram per minute until the limit of tolerance of the individual patient was reached. The infusion was maintained at this level until the end of a one and one quarter hour period.

Tolerance and Untoward Effects—Tolerance was inversely proportional to the initial blood pressure. In the majority of instances, maximum tolerance was determined by the occurrence of unpleasant subjective reactions, including anxiety, tremor, heart consciousness and headache. One subject in the series complained of mild substernal pain which subsided without sequelae when the infusion was stopped. Cardiac irregularity, due to premature contractions, occurred to some degree in nearly all patients. In one instance it was sufficiently marked to dictate the cessation of the infusion.

Three persons developed cerebral symptoms, characterized in one by intense headache and momentary syncope, in another by transient unconsciousness, and in the third by a hemiplegic syndrome without loss of consciousness, from which recovery was complete in twelve hours. In two of these instances the reaction occurred during administration of the initial dose of adrenalin. These alarming episodes, which resembled the encephalopathic manifestations seen in pheochromocytoma,²¹ occurred during the later phase of these studies and influenced their termination.

Analytic Methods—The subjects were divided into four groups on the basis of the initial diastolic blood pressure level. The pressure range from 51 to 70 mm Hg included thirteen subjects, 71 to 90 mm, seventeen subjects, 91 to 110 mm, sixteen subjects, and 111 to 130 mm, five subjects.

The mean group values of the blood pressure, pulse rate, change in pressure and pulse rate, and the systolic diastolic pressure ratio were computed for each range of dose tolerated by two or more of the subjects in a group. The pressure and pulse values which corresponded to the highest systolic pressure observed at each dose level were used in making computations.

Variability of response was estimated in terms of the standard deviation from the mean, corrected for small samples, while the significance of differences between groups were determined by calculation of the *t* value, which indicates the probability that the observed differences did not arise by chance.

The presence of linear relationship between variables was evaluated by calculation of the correlation coefficient.

RESULTS

The sequence of events in the course of an adrenalin infusion is illustrated in Fig 1. During the first few minutes a period existed in which the incoming adrenalin solution was diluted by the saline in the tubing which connected the stopcock to the infusion needle. In this period the systolic pressure, diastolic pressure, or both ordinarily manifested a fall followed by a sharp rise when undiluted solution reached the circulation. This rise usually elevated the systolic and occasionally the diastolic pressure above the preinfusion value.

Fig 1—The effects of a continuous infusion of adrenalin on pulse rate and blood pressure (Subject J. C.). Solid circles systolic blood pressure, open circles diastolic blood pressure, dotted line pulse rate.

An increase in the rate of administration produced a further rise in systolic and diastolic pressures to a new maximum in one to three minutes. The net result of successive increases in dosage was a steplike curve of pressure change.

In most instances infusion of adrenalin resulted in cardiac acceleration (Table II). The increase in rate usually was most marked at the lowest dosage range where it appeared roughly proportional to the initial pressure. Less than 25 per cent of subjects manifested at any time a fall in rate below the preinfusion value.

TABLE II CHANGES IN PULSE RATE IN RELATION TO INITIAL DIASTOLIC BLOOD PRESSURE AT VARIOUS RATES OF ADRENALIN ADMINISTRATION

INITIAL DBP RANGE	AVERAGE INITIAL PULSE	CHANGES IN PULSE RATE (BEATS/MIN./ μ C/KC./MIN.) AND STANDARD DEVIATION										
		RANGE OF ADRENALIN DOSE (μ C/KC./MIN.)										
		0.11 - 0.20	0.21 - 0.30	0.31 - 0.40	0.41 - 0.50	0.51 - 0.70	0.71 - 0.90	0.91 - 1.10	1.11 - 1.30	1.31 - 1.50		
51 - 70	85	7 \pm 47	11 \pm 31	14 \pm 34	14 \pm 34	14 \pm 34	-1 \pm 17	8 \pm 19	10 \pm 16	1 \pm 4		
71 - 90	82	32 \pm 65	32 \pm 41	25 \pm 44	25 \pm 44	25 \pm 44	22 \pm 14	18 \pm 11	12 \pm 17	17 \pm 22		
91 - 110	80	54 \pm 55	59 \pm 45	33 \pm 24	33 \pm 24	33 \pm 24	15 \pm 21					
111 - 130	82	55 \pm 67	37 \pm 31	27 \pm 21	27 \pm 21	27 \pm 21						

Following cessation of infusion both systolic and diastolic pressures dropped abruptly. A minimum level was reached usually by the tenth and not later than the fifteenth minute after clamping the infusion tubing. These minimum levels were lower than the initial blood pressure levels in all but one instance and were accompanied by cardiac acceleration.

Results of Repeated Infusion—Observations on the diminished effectiveness of chronic adrenalin administration in allergic disorders, coupled with reports of desensitization phenomena in patients treated for anxiety states by repeated adrenalin administration,² prompted a study of the effects of daily infusion.

Fig. —The blood pressure responses to daily infusion of adrenalin (Subject J. B.). Size of circle indicates temporal sequence. For clarity the curves of every second day only are shown. Solid circles, systolic blood pressure; open circles, diastolic blood pressure.

Five subjects were used in this portion of the investigation. One was infused on twelve successive days, a second on ten, another on four, and two on three days. Despite some variation in the initial level of blood pressure from day to day, the slopes of the pressure response curves appeared almost identical within limits of the experimental method as illustrated in Figs. 2 and 3. For clarity, the curves of alternate days only are presented.

Fig 3 —The blood pressure responses to daily infusion of adrenalin (Subject J S) Size of circles indicates temporal sequence For clarity the curves of every second day only are shown Solid circles systolic blood pressure open circles diastolic blood pressure

Fig 4 —Average blood pressure responses to adrenalin in subjects grouped on the basis of initial diastolic pressure Solid circles systolic blood pressure open circles diastolic blood pressure

Although objective responses remained reasonably constant, increase in the subjective limit of tolerance was marked. The patient infused on twelve days accepted a dose on the last day which was ten times larger than that tolerated on the first day.

Net Pressure Changes in Relation to Perfusion Pressure—The action of adrenalin on both systolic and diastolic pressures was characterized by a wide range of variation between individuals in the same group.

A mean rise in systolic pressure in all groups at all levels of dosage was produced as illustrated in Fig. 4. The pressure curves tended to parallel one another despite the differences in initial tension.

At the lowest level of dosage a mean fall in diastolic blood pressure was observed which was more marked the higher the initial pressure. Successive increments in dosage produced a rise in pressure at a rate roughly parallel in the four pressure groups.

The diastolic fall at low adrenalin dosages in the face of an increase in pulse rate suggested that systolic elevation was achieved through cardiac stimulation which overbalanced a compensatory drop in peripheral resistance. Such a drop in resistance might have resulted from moderator nerve activity alone or in conjunction with a direct dilator action of adrenalin. Whatever the nature of the compensatory mechanism, its value was limited to much the same extent in all groups as evidenced by the transition to diastolic elevation at dosages in excess of 0.30 μg per kilogram per minute.

Unit Pressure Changes in Relation to Perfusion Pressure—The rise in systolic pressure per microgram of adrenalin tended to correlate both with increase in pulse rate and with perfusion systolic pressure over a restricted range of initial tensions, the upper limit of which lay between 180 and 200 mm Hg. However, when the unit systolic changes over the entire range were compared on a group basis (Table III, Fig. 5) the differences in mean response between groups did not prove significant. The *t* values for the differences ranged from 0.45 to 1.45.

TABLE III. CHANGES IN BLOOD PRESSURE IN RELATION TO INITIAL DIASTOLIC BLOOD PRESSURE AT VARIOUS RATES OF ADRENALIN ADMINISTRATION

INITIAL P. RANGE	AVERAGE INITIAL SBP	A. CHANGES IN UNIT SYSTOLIC BLOOD PRESSURE (MM Hg/ $\mu\text{g}/\text{kg}/\text{MIN}$) AND STANDARD DEVIATION						
		RANGE OF ADRENALIN DOSAGE ($\mu\text{g}/\text{kg}/\text{MIN}$)						
		0.11 0.30	0.31 0.50	0.51 0.70	0.71 0.90	0.91 1.10	1.11 1.30	1.31 1.50

range		106 \pm 96	91 \pm 62	80 \pm 38	80 \pm 17	69 \pm 14	69 \pm 16	57 \pm 12
INITIAL P. RANGE	AVERAGE INITIAL DBP	B. CHANGES IN UNIT DIASTOLIC BLOOD PRESSURE (MM Hg/ $\mu\text{g}/\text{kg}/\text{MIN}$) AND STANDARD DEVIATION						
		RANGE OF ADRENALIN DOSAGE ($\mu\text{g}/\text{kg}/\text{MIN}$)						
		0.11 0.30	0.31 0.50	0.51 0.70	0.71 0.90	0.91 1.10	1.11 1.30	1.31 1.50
51-70	65	-11 \pm 36	1 \pm 23	9 \pm 17	13 \pm 12	16 \pm 8	16 \pm 7	15 \pm 4
71-90	81	-14 \pm 33	0 \pm 28	8 \pm 7	16 \pm 10	21 \pm 5	17 \pm 9	16 \pm 1
91-110	98	-23 \pm 24	5 \pm 34	10 \pm 24	1 \pm 22			
111-130	121	-40 \pm 28	-28 \pm 26	-15 \pm 21				
range		-19 \pm 33	-2 \pm 20	9 \pm 19	12 \pm 13	17 \pm 7	16 \pm 8	15 \pm 3

When the degree of activity at various dosages was computed, it became evident that adrenalin was decreasingly effective in its ability to elevate the systolic pressure as the rate of administration was increased. The over all unit response was halved with a sixfold rise in dose, while the maximum response which averaged 106 mm Hg per microgram, was observed at the lowest dosage range.

Fig. 5—Average unit blood pressure responses to adrenalin in subjects grouped on the basis of initial diastolic pressure. Size of circles indicates the relative magnitude of the initial pressure range. Solid circles—systolic blood pressure; open circles—diastolic blood pressure.

Comparison of changes in unit diastolic pressure (Table III, b, Fig. 5) demonstrated a fall at the lowest rate of administration which appeared inversely proportional to the initial pressure, but the coefficient of correlation (-0.229) was not significant. Succeeding increases in rate resulted in a rise to a maximum value of 17 mm Hg per microgram at an average dose of $10 \mu\text{g}$ per kilogram per minute, a value which showed little further change at higher dosage levels where a comparison between groups was possible.

After allowance was made for the wide range of individual variation there was evident a common pattern of reaction characterized by pressure changes similar in directions and magnitudes in each of the four pressure groups but different in the pressure base lines from which projected.

Effects on the Systolic-Diastolic Pressure Relationship—The similarity of the unit pressure changes in each group suggested that adrenalin was modifying some relationship between systolic and diastolic pressure which was largely independent of the absolute height of the pressure. To explore this possibility calculations were made of the correlation coefficient between systolic and diastolic pressures initially and at each dosage level. The value of the coefficient

(Table IV) averaged 0.80 which indicated the probability that the two pressures were related by a fairly constant factor. The magnitude of this factor was estimated by determining the systolic diastolic ratios at each rate of administration.

TABLE IV CORRELATION BETWEEN SYSTOLIC AND DIASTOLIC BLOOD PRESSURES AT VARIOUS RATES OF ADRENALIN ADMINISTRATION

DOSE RANGE (μ /KG/MIN.)	CORRELATION COEFFICIENT
0	0.817
0.11-0.20	0.754
0.1-0.50	0.793
0.51-0.70	0.781
0.71-0.90	0.814
0.91-1.10	0.718
1.11-1.30	0.885
1.31-1.50	0.829
Average	0.800

The perfusion ratio averaged 1.7 ± 0.27 and did not vary materially among the four pressure groups. The size of this ratio was somewhat surprising for its value at normal pressures is usually stated to approximate 1.5 while the increased peripheral resistance in hypertensive subjects is expected to exaggerate the diastolic pressure⁴ and yield a ratio lower than normal. However, a calculation of this ratio from data reported by Steele for a group of thirty-nine patients whose blood pressures ranged from 94 mm Hg systolic, 60 mm diastolic to 262 mm systolic 164 mm diastolic gave an average value of 1.72 ± 0.10 . Similar calculations were made from Golding and

Fig. 6—Average change in systolic diastolic ratio produced by adrenalin in subjects grouped on the basis of initial diastolic pressure. Size of circle indicates the relative magnitude of the initial blood pressure range.

Chasis data¹ relative to fifty-six patients with mild to severe hypertension. The ratio of this latter group averaged 1.59 ± 0.19 for both minimum and maximum recorded pressures.

At the lowest rate of adrenalin administration, the systolic diastolic ratio in the present series increased to an average value of 2.21 ± 0.38 . This new value was also similar in all pressure groups and tended to remain constant with succeeding increments in dosage. These relations are illustrated in Fig 6 and their variability indicated in Table V. The *t* value (9.78) for the difference in ratio before and during infusion at the lowest dose range indicated the change to be highly significant.

TABLE V. SYSTOLIC-DIASTOLIC PRESSURE RATIO IN RELATION TO INITIAL DIASTOLIC BLOOD PRESSURE AT VARIOUS RATES OF ADRENALIN ADMINISTRATION

INITIAL DBP RANGE	RANGE OF ADRENALIN DOSAGE ($\mu\text{G/KG/MIN}$)							
	0	0.11-0.20	0.21-0.50	0.51-0.70	0.71-0.90	0.91-1.10	1.11-1.30	1.31-1.5

TABLE V SYSTOLIC DIASTOLIC PRESSURE RATIO IN RELATION TO INITIAL DIASTOLIC BLOOD PRESSURE, VARIOUS RATES OF ADRENALIN ADMINISTRATION

INITIAL DBP RANGE	RANGE OF ADRENALIN DOSAGE ($\mu\text{G/KG/MIN}$)								c
	0	0.11-0.30	0.31-0.50	0.51-0.70	0.71-0.90	0.91-1.10	1.11-1.30	1.31-1.50	
51-70	1.2 ± 0.21	2.25 ± 0.25	2.26 ± 0.31	2.23 ± 0.28	2.26 ± 0.31	2.16 ± 0.25	1.98 ± 0.32	1.98 ± 0.32	
71-90	1.5 ± 0.26	2.22 ± 0.53	2.21 ± 0.47	2.14 ± 0.38	2.16 ± 0.13	2.02 ± 0.50	2.23 ± 0.15	2.25 ± 0.15	
91-110	1.2 ± 0.34	2.20 ± 0.35	2.13 ± 0.38	2.12 ± 0.30	2.20 ± 0.39				
111-130	1.71 ± 0.07	2.07 ± 0.07	2.25 ± 0.13	2.20 ± 0.12					
Average	1.73 ± 0.27	2.21 ± 0.38	2.21 ± 0.37	2.17 ± 0.31	2.22 ± 0.26	2.10 ± 0.30	2.12 ± 0.24	2.10 ± 0.24	

It would appear likely that this increase in systolic-diastolic ratio reflects a readjustment in the relation of peripheral resistance to cardiac output which results from adrenalin action and is relatively independent of the initial pressure.

Postinfusion Fall in Pressure—When blood pressure is raised by application of a pressor agent which can be quickly destroyed, it is anticipated that the pressure will return at least to the initial level when the pressor agent is no longer supplied. In order to avoid such spurious correlations, all calculations involving the fall which followed adrenalin infusion were based on the amount by which the blood pressure dropped below the preinfusion level.

Computed on this basis, the postinfusion fall in both systolic and diastolic blood pressures was found to correlate more closely with the height of the initial blood pressure than with rise in pressure, maximum pressure, dose or maximum unit change in blood pressure, as shown in Table VI.

TABLE VI CORRELATION BETWEEN FALL IN POSTINFUSION BLOOD PRESSURE BELOW INITIAL LEVEL AND VARIOUS MODIFYING INFLUENCES

FALL IN BLOOD PRESSURE AND	COEFFICIENT OF CORRELATION (SYSTOLIC PRESSURE)	COEFFICIENT OF CORRELATION (DIASTOLIC PRESSURE)
Initial pressure	-0.598	-0.491
Maximum pressure	-0.500	-0.307
Maximum change in pressure	0.032	0.134
Dose	-0.389	-0.117
Change in unit pressure	0.079	0.239

In general, the higher the patient's initial pressure, the further did the pressure drop below the initial level when the infusion was stopped. The extent of this relation is illustrated in Figs 7 and 8. In a number of instances the

Fig 7—The relation between initial systolic pressure and the postinfusion fall below initial pressure. The lines of regression from the X and Y axes are indicated.

Fig 8—The relation between initial diastolic pressure and the postinfusion fall below initial pressure. The lines of regression from the X and Y axes are indicated.

minimum pressures came within the range usually associated with shock. Except for tachycardia, however, no other signs of shock were noted. The subjects remarked about a sensation of heat and manifested a widespread vasodilatation by a generalized flushing of the skin. Tilting during the stage of blood pres

sure depression was followed by considerable acceleration of the pulse rate and in one instance by syncope. The reactions to tilting were similar to the ones which follow bleeding.²⁶

The cause of the postinfusion drop in tension to subnormal levels is questionable. The depression of pressure in association with evidences of vasodilatation suggests a temporary persistence of compensatory vasodepressor activity, either nervous or humoral. The presence of postural vasomotor reflexes makes it unlikely that adrenalin blockage of sympathetic ganglia²⁷ is the responsible factor. The tendency of the hypertensive subjects to display a more marked postinfusion pressure depression accords with the results of carotid sinus stimulation.¹

The possible role of blood volume changes is considered in connection with blood concentration.

Alterations in Hemoconcentration—Two potential mechanisms exist by which adrenalin might alter blood concentrations. The first involves splenic contraction followed by extrusion of sequestered red cells and an increase in their percentage in the circulating blood.^{22a, 23, 24, 28} The second possibility implicates leakage of plasma through capillaries made more permeable by stagnant anoxia following prolonged vasoconstriction.²⁹

These possibilities were studied by using the hematocrit value as an indicator of blood concentration. The results of determinations made during and after infusion were compared with the initial values. No significant changes were demonstrated at either stage within the range of dosage used (Table VII).

The constancy of the hematocrit value makes it unlikely that the postinfusion blood pressure depression displayed by the subjects of this investigation was due to a reduction in plasma volume comparable to that produced in dogs by Freeman and co-workers through administration of adrenalin in shock dosages.³⁰

TABLE VII EFFECTS OF ADRENALIN INFUSION ON BLOOD CONCENTRATION

TIME	HEMATOCRIT VALUE (vol %)
a Average Values	
(1) Before infusion	39
(2) During infusion	40
(3) After infusion	39
b Standard Deviations of the Differences in Mean Hematocrit Value During and After Infusion as Compared with Preinfusion Average	
d (1) and (2)	1 ± 2.9
d (1) and (3)	0 ± 3.7

SUMMARY AND CONCLUSIONS

Administration of eighty continuous infusions of adrenalin to fifty-one subjects evoked a common pattern of systolic and diastolic response of all ranges of initial pressure.

The correlation between the height of the initial pressure and the depth of the subsequent postinfusion depression provides additional data that the vasodilator capacity of the hypertensive individual is enhanced rather than diminished.

The sum of these responses to adrenalin together with the extent of the fall produced by carotid sinus stimulation spinal anesthesia pyrogens and the tetraethylammonium ion indicates that 'fixed hypertension' in the sense of a pressure elevation incapable of material reduction is a concept of questionable reality. On the contrary the accumulated evidence demonstrates the availability of compensatory mechanisms in the hypertensive subject and the capacity of the vascular apparatus to respond effectively when these mechanisms are properly stimulated.

The existence of pressure elevation in the presence of potentially effective restorative mechanisms suggests that sustained hypertension is associated like fever, with an upward shift in the base line from which the homeostatic mechanisms are operative. The problem then is to determine the factor or factors responsible for the elevation of the pressure base line to this new level.

THE EFFECT OF OPERATION AND ILLNESS ON CLOT RETRACTION DESCRIPTION OF A NEW METHOD

JOHN S. HIRSCHBOECK, M.D.
MILWAUKEE, WIS.

LAMPERT,¹ in 1935, indicated the possible role which accelerated clot retraction may play in phlebotrombosis and pulmonary embolism. Hirschboeck and Coffey have recently demonstrated that a shortening of the clot retraction time occurs in patients who have had a recent pulmonary embolism. Because of the difficulty in observing the end point in the usual blood coagulation and clot retracting tests, it was decided to search for a more simple and decisive method of observation. The coagulation retraction test herein described has been found to be more useful than the older methods and was used in obtaining the data for this report.

Clot retraction is dependent upon thrombocyte surface forces, erythrocyte mass and qualitative and quantitative variations in fibrin. Other factors as yet unknown, also may influence the process. It is common knowledge that clot retraction is greatly delayed or does not occur when thrombocytopenia is present. Thrombocytosis is, on the other hand, associated with rapid clot retraction.²

It is not known how the thrombocytes actually participate in the phenomenon. Tocantins' explanation that the agglutinated, disintegrating thrombocytes which collect and adhere to the fibrin strands fuse with adjacent thrombocyte masses thus causing the gradual pulling together of the fibrin mesh, has been widely accepted.³

The surface with which the clot is in contact greatly influences the retraction. A collodion surface is completely inhibitory.⁴ Paraffin, methyl methacrylate and other water repellent materials which inhibit coagulation also more or less inhibit clot retraction. The surface of the vascular endothelium apparently exerts a similar effect. These surfaces may act because of their ability to inhibit platelet agglutination or because the fibrin becomes more firmly attached to the surface.⁵

Erythrocytes influence clot retraction in two ways. First, when the concentration as measured by the hematocrit is abnormally great, for example 80 per cent (a value frequently seen in congenital heart disease with chronic anoxemia) clot retraction does not occur. The mass of erythrocytes which incidentally, has an entirely passive role in coagulation limits the degree of retraction by the volume which it occupies in the clot. Second, when the erythrocyte mass is large the plasma volume and hence the total amount of fibrinogen, is proportionately small. The opposite condition prevails in anemia. Here the small erythrocyte mass interferes less with clot retraction and the clot

Fig. 1.—The effect of surface on platelet disintegration and fibrin formation. The upper photograph was taken one hour after plasma from freshly drawn centrifuged human blood was placed on a glass surface (microscope slide and cover slip). Note the disintegrating platelets and the numerous delicate fibrin strands. The large bodies are erythrocytes. The lower photograph demonstrates the effect of a collodion surface on the same specimen of plasma. The platelets are intact and highly refractile and the fibrin strands are heavier and more numerous.

contains more fibrin because of the relative or even absolute hyperfibrinogenemia. Thus anemic blood exhibits a tendency toward more rapid and extensive clot retraction. A fibrinogen fraction which greatly accelerates erythrocyte sedimentation and is converted into rapidly retracting fibrin (contractinogen)⁶ may be present. These qualitative and quantitative increases in fibrin which occur during illness are responsible not only for increasing the rate of erythrocyte sedimentation but also for producing denser and more retractile clots.

A study of the thrombotic diathesis or, as some prefer to say, hypercoagulability, must include more than the mere measurement of coagulation time. A method which will measure indirectly the combined effect of anemia, thrombocytosis, and hyperfibrinogenemia in addition to any other factor which may express itself in a shortened coagulation time, should be valuable. Earlier observations of the clot retraction time form the basis for much of the present work. A new method using capillary blood has been devised. It has the advantages of eliminating venipuncture and of having a more precise end point.

METHOD FOR DETERMINING THE CLOT RETRACTION TIME IN CASTOR OIL

The skin of the finger tip is cleansed with alcohol and a puncture 3 mm deep is made with a No. 11 Bard Parker blade with a coil guard set 3 mm from the tip. The time is recorded when the skin puncture is made. Two samples of blood (20 cmm each) are drawn as quickly as possible into Sahli hemoglobinometer pipettes. The same pipette may be used for each sample if the blood flows freely and the aspiration is done quickly. Each sample of blood is suspended in a separate test tube filled with castor oil U. S. P. in the following manner. The blood is expelled from the pipette as a large single drop which is planted on the center of the oil surface by touching the tip of the pipette to the oil. The drop will settle into the oil and hang by surface attraction to the meniscus. Castor oil was selected because its specific gravity at room temperature is almost the same as the specific gravity of blood. The tubes are stoppered to prevent evaporation. This procedure should not take longer than twenty seconds. Two samples are used for purposes of control. If the clot retraction time is not equal or within three minutes of being equal in both tubes, the test is repeated. This is seldom necessary. The tubes are placed in a rack at room temperature and are observed at the end of ten, fifteen, and twenty minute periods. The end point of coagulation is not determined. The beginning of clot retraction is established when a visible dimpling of the clot surface with extrusion of a tiny droplet of serum occurs. It is usually readily seen because of the highly retractile oil blood interface. This is the end point of the test. The droplet of serum enlarges until clot retraction is complete (Figs. 2 and 3). For investigative purposes, the preparations were observed continually.

It was found that normal individuals have a clot retraction time of 20 minutes or longer, the average being 33.1 minutes. Clot retraction times longer than 50 minutes were observed only in thrombocytopenia and erythremia and in persons with a coagulation defect. The clot retraction time may fluctuate during the course of the day in some individuals. The moving of patients in

The sequence of photographs showing the lateral aspect of a bull of a breed of about 1000 lb. The bull is in a dark environment, possibly a room or a vehicle. The photographs are arranged horizontally, with 1 on the left, 2 in the middle, 3 on the right, 5 on the left, 6 in the middle, 7 in the middle, and 8 on the right.

Fig 3—Three types of serum buds observed when a drop of capillary blood coagulates and retracts in capillary oil

and out of bed has been associated with fluctuations of more than 8 minutes in some of the more senile individuals. It is thought that this may be due to minor variations in thrombocyte levels. The clot retraction time is shorter at 37°C . Variations in room temperature have not appreciably influenced the results. Room temperature was selected for the test because the drops of blood frequently fall in the oil at 37°C .

Fig 4—Normal variations in the coagulation retraction time in a series of one hundred normal individuals

The clot retraction time was determined in a series of fifty normal men and fifty normal women. Hospital attendants, nurses, and medical students were used as subjects. The mean clot retraction time for men was 32.4 minutes and for women was 33.8 minutes, or 33.1 minutes for the group as a whole (Fig 4). It was noticed that active menstruation slightly shortened the clot retraction time. Eleven women had a mean clot retraction time of 27.6 minutes during active menstruation and 34.7 minutes during the intermenstrual period.

Fig 5—The shift to the left in coagulation-retraction times observed in three hundred general medical patients

Fig 6—Postoperative variations in the incidence of short (pathologic 20 minutes or less) coagulation-retraction times

Observations in the general hospital patient population, excluding patients in the first postoperative month revealed that the mean clot retraction time was shorter than in healthy persons (Fig 5). The mean clot retraction time for one hundred fifty two men was 24.9 minutes and for one hundred forty eight women, 22.6 minutes, or 23.8 minutes for the total group (three hundred). The clot retraction time was less than 20 minutes in 23.7 per cent and less than 15 minutes in 7.6 per cent of the group.

Fig 7—A comparison between the coagulation retraction times of normal and postoperative patients. The cross ruled area represents the distribution region common to both groups.

One hundred surgical patients were observed during the postoperative period. The majority had undergone major abdominal surgery. Fig 6 shows the tendency of the clot retraction time to fluctuate during the postoperative period. Of the tests performed on the day of surgery, 33.5 per cent were faster than normal. This may be explained by the hyperfibrinogenemia resulting from the stimulus of surgical trauma and perhaps dehydration. The percentage of abnormally short clot retraction times was also high on the third, fourth, and fifth and on the ninth and subsequent postoperative days. Fig 7 is a comparison between the clot retraction time of fifty three patients in their twelfth post

operative day with one hundred normal individuals. Seventy six of the one hundred postoperative patients had an abnormally short clot retraction time on one or more days during the period. In thirty of the patients the clot retraction time was shorter than 15 minutes on one or more days.

DISCUSSION

In the past, great emphasis has been placed on vascular endothelial trauma and delayed circulation time as factors in the cause of phlebothrombosis and pulmonary embolism. Since the introduction of anticoagulant therapy more attention has been given to the blood itself. The thrombotic diathesis apart from slowing of circulation time and vascular trauma, is entirely dependent upon hemie factors, namely thromboexiosis, hyperfibrinogenemia, and diminished erythrocyte mass. These factors may enhance coagulation, but their more important effect lies in their creation of a strongly retracting, tough clot which is susceptible to embolic detachment because of its retractility.

One of the patients in the nonsurgical group, a woman who had recently been digitalized for early total myocardial failure, developed pulmonary embolism when her clot retraction time was 11 minutes. The clinical picture was typical and the radiographic examination of the chest and the electrocardiogram sustained the diagnosis. This was the only instance of pulmonary embolism encountered during the entire study. A correlation between the clot retraction time in castor oil and the tendency toward pulmonary embolism is implied in this case. Likewise the shortening of the clot retraction time in bedridden patients may help to explain the tendency toward pulmonary embolism prevalent in that group. If we can assume that patients with short clot retraction times are more susceptible to thrombosis and embolism, it may be desirable to treat those persons prophylactically with anticoagulants.

The clot retraction test is well adapted to the control of heparin therapy and can be used instead of the ordinary coagulation time determinations. It is not reliable during Dicumarol therapy. The test is really a measure of the coagulation time plus the interval between the end of coagulation and the beginning of clot retraction. Heparin, since it prolongs coagulation and in some instances inhibits the postcoagulation phase, will greatly lengthen the time of the test. Dicumarolization frequently prolongs the clot retraction time, but there is no correlation between this effect and the prothrombin time.

SUMMARY

A test for measuring the blood clot retraction time in castor oil is described.

The clot retraction time is considerably shorter than normal in certain patients who are in the postoperative period and in almost one fourth of all general medical patients.

The test measures factors which are part of the hemie phase of the thrombotic diathesis.

LABORATORY METHODS

A SIMPLIFIED TECHNIQUE FOR THE QUANTITATIVE COLORIMETRIC ESTIMATION OF PREGNANDIOL IN URINE

HENRY S. GUTERMAN, M.D., AND MADELINE S. SCHROEDER, B.S.
CHICAGO, ILL.

PREVIOUSLY this laboratory reported a simple method for the qualitative determination of urinary pregnandiol by its reaction with concentrated sulfuric acid^{1, 2}. The present report deals with the study of the pregnandiol color reaction which permits its simple quantitative measurement in a colorimeter.

REAGENTS

Toluene, chemically pure

Concentrated hydrochloric acid, chemically pure

0.1 N sodium hydroxide

Two per cent sodium hydroxide in absolute methanol. A 4 to 8 per cent solution of sodium hydroxide in absolute methanol is first prepared by adding sodium hydroxide pellets to an Erlenmeyer flask containing absolute methanol. The mixture is filtered through a dry fritted glass filter to remove the precipitated carbonate. The sodium hydroxide concentration of the filtrate is determined by titration with 0.1 N sulfuric acid. The filtrate is then adjusted to a concentration of 2 per cent with absolute methanol. The solution is freshly prepared every week.

Acetone, chemically pure

Absolute ethyl alcohol

Concentrated sulfuric acid, chemically pure

TECHNIQUE*

A. Hydrolysis and Excretion of Pregnanediol —

1. One hundred milliliters urine, 50 ml. toluene, 10 ml. concentrated hydrochloric acid, and two glass beads are added to a 500 ml. flat-bottomed Florence flask.

Department of Metabolism and Endocrinology, Research Institute, Michael Reese Hospital. The department is in part supported by the Michael Reese Research Foundation. This work was aided by a grant from the Committee on Scientific Research of the American Medical Association to Dr. Rachmiel Levine.

Received for publication Dec. 5, 1947.

*Based upon the method for pregnandiol extraction by Astwood and Jones³ and the color reaction of Talbot and co-workers.⁴

2 The flask is connected via a one holed cork stopper to a Liebig condenser (water-cooled 400 to 500 mm jacket length) in vertical position and the mixture is boiled vigorously over an electric hot plate for fifteen minutes

3 The flask and its contents are brought to room temperature by cooling under the water tap

4 The mixture is transferred to a 500 ml separator funnel and the lower layer (urine) is drawn off

5 The toluene layer and emulsion are washed twice with 15 ml portions of 0.1 N sodium hydroxide and then twice with 15 ml portions of distilled water

B Precipitation of Impurities —

1 The washed toluene and emulsion (A 5) are transferred to a 125 ml Erlenmeyer flask with two glass beads

2 The mixture is boiled over an electric hot plate (in the hood)

3 When the water has evaporated and the toluene mixture is boiling smoothly 10 ml of 2 per cent sodium hydroxide in absolute methanol are added

4 The mixture is evaporated until a granular precipitate appears and approximately one half of the original toluene volume is reached

5 The toluene mixture is then filtered while hot through a fritted glass filter (medium porosity Pyrex) with mild suction (If the filtrate has an orange pink or brown tinge steps B 3, B 4 and B 5 must be repeated until the filtrate is yellow or yellow green)

6 The precipitate (B, 5) is washed with 15 ml hot toluene

7 The combined filtrates (B 5 and B 6) are then evaporated to dryness over the hot plate (in the hood) a gentle air stream being used to drive off the last traces of toluene This avoids charring of the residue

C Precipitation of Pregnandiol —

1 Five milliliters acetone are added to the residue (B 7) and the mixture is warmed over a hot plate until solution is complete

2 Twenty milliliters 0.1 N sodium hydroxide are added slowly and the mixture is boiled for three minutes on the hot plate

3 The flask is then placed in a refrigerator (5° C) for one hour

D Isolation of Pregnandiol —

1 The mixture (C 3) is filtered through a fritted glass filter (medium porosity Pyrex) with mild suction

2 The precipitate (D, 1) is washed with 15 ml distilled water

3 The receiving flask is changed and 10 ml hot absolute alcohol are passed through the fritted glass filter to dissolve the precipitate

4 The alcohol filtrate (D 3) is evaporated to dryness from the receiving flask over an electric hot plate (in the hood)

E Color Development and Quantitative Measurement —

1 Ten milliliters concentrated sulfuric acid are added to the residue (D 4)

2 Color is allowed to develop for one hour

3 An aliquot of the solution E, 2 is diluted up to a final volume of 5 ml with concentrated sulfuric acid in a dry absorption tube (Cenco No 1234M tubular cell) and the solution is thoroughly mixed

4 The color is read on a spectrophotometer* at 430 $m\mu$ (concentrated sulfuric acid is used as the blank)

5 The amount of pregnandiol represented by the absorption reading is obtained from the standardization curve. Calculations for the dilutions involved are made to ascertain the pregnandiol present in the original sample

EXPERIMENTAL

The evidence that pregnandiol is the steroid extracted by this procedure is based on the spectrophotometric absorption and the melting point data which follow

Fig 1—Absorption curves of color complexes obtained from the addition of concentrated sulfuric acid to crystalline pregnandiol and pregnandiol recovered from urine

Pregnancy urine pooled female urine to which sodium pregnandiol glucuronide (NaPG)[†] was added, and pooled female urine to which pregnandiol was added were subjected to the foregoing procedure. The absorption spectra of the color complexes obtained with these specimens and the absorption spectra

*The Cenco-Sheard Spectrophotometer Central Scientific Company Chicago Ill was used in the present study

[†]Sodium pregnandiol glucuronide will be designated as NaPG in the succeeding paragraphs

trum of crystalline pregnandiol to which concentrated sulfuric acid had been added were compared. Fig 1 illustrates the four curves. They resemble one another closely and demonstrate an absorption maximum between 420 and 440 millimicrons.

The melting points of the products recovered in this experiment are listed below.

- 1 Pregnancy urine, 205 to 215° C
- 2 NaPG added to pooled female urine 215 to 227° C

Fig 1—Absorption curves of the products recovered from urine to which various steroids had been added.

- 3 Pregnandiol added to pooled female urine, 227 to 233° C
- 4 Crystalline pregnandiol, 234.5 to 237° C

When the recovered substances (from 1, 2, and 3) were each mixed with pure pregnandiol there was no depression of the melting point.

The absorption curves of other steroids commonly found in urine were studied in similar fashion. Androsterone, cholesterol, α -estradiol, estrinol, estrone and pregnandiol,* 100 μ g of each in toluene solution, were added to 100 cc samples of pooled female urine and the mixture was run through the recommended procedure. Fig 2 illustrates the absorption curves obtained. It appears from these data that the steroids tested do not significantly alter the absorption curve (at the given wave lengths) of the pooled female urine used as a control. Only the specimen with added pregnandiol demonstrated a marked increase in absorption with a maximum at 430 millimicrons.

These data appeared to indicate that the method outlined leads to the recovery of pregnandiol alone.

Optimal conditions for the quantitative extraction of pregnandiol from urine and the maximal final color development were established by the following experiments.

I Duration of Simultaneous Hydrolysis and Extraction—NaPG (aqueous solution) 2 mg, was added to 100 ml portions of pooled female urine†. The specimens were refluxed for five, fifteen, and thirty minutes each and then carried through the procedure. The results obtained indicated that maximal extraction of pregnandiol occurs if the urine mixture is refluxed for fifteen minutes. Five minutes of boiling appeared inadequate for optimal recovery of pregnandiol. Refluxing for thirty minutes did not interfere with the maximal recovery. It was therefore concluded that specimens should be refluxed for at least fifteen minutes.

II Efficiency of One Period of Hydrolysis and Extraction—Toluene 50 ml was added to the urine layers of the specimens (I) which had been hydrolyzed and extracted for fifteen minutes. Some of the samples were extracted in the cold for fifteen minutes on a mechanical shaker. The remainder were refluxed for an additional fifteen minutes as in the original procedure. The toluene layers were saved and carried through the technique. The absence of color development at step B, 2 indicated that in the first period of boiling the extraction of urinary pregnandiol was complete.

III The Effect of Aqueous Sodium Hydroxide—

A A series of specimens were carried to step A, 5. At that point the toluene layers were each washed with one, two, and four 15 ml portions of 0.1 N sodium hydroxide. The technique was then followed as outlined. The results of this experiment showed that at least two washings of the toluene layer with 0.1 N sodium hydroxide are necessary for uniform neutralization. Additional washings with 0.1 N sodium hydroxide did not affect pregnandiol recovery.

B The combined sodium hydroxide and water washings of the specimen (III A) were diluted to a volume of 100 ml with distilled water. Ten milli-

*The androsterone, α -estradiol, estrinol and estrone were supplied through the courtesy of Ciba Pharmaceutical Products, Inc., Summit, N. J. The pregnandiol and sodium pregnandiol glucuronide were generously supplied by Ayerst McKenna and Harrison Ltd., Montreal, Canada.

†Unless otherwise indicated in the following experiments 2 mg sodium pregnandiol glucuronide were added to 100 ml portions of pooled female urine. All tests were carried out in duplicate.

liters hydrochloric acid (concentrated) and 50 ml of toluene were added. These mixtures were carried through the procedure (starting at A 1). No color development occurred in any specimen. Thus, it appeared that the sodium hydroxide originally used did not remove pregnandiol from the toluene layer.

IV Precipitation of Impurities by 2 Per Cent Sodium Hydroxide in Absolute Methanol —

A One hundred milliliter portions of pooled female urine to which no NaPC was added were carried to step B 3. At that point, 0.5, 10, 20 and 30 ml aliquots of 2 per cent sodium hydroxide in absolute methanol were added and the procedure was completed. When the methanolic sodium hydroxide solution was not employed, the red and violet urinary pigments extracted by the toluene were not removed from solution and they interfered with the final color reaction by producing bizarre colors. The use of sodium hydroxide in methyl alcohol removed these urinary pigments and resulted in constant final color development. Therefore it was concluded that methanolic sodium hydroxide should be employed at this stage.

B When the same experiment was carried out with urine specimens to which NaPC had been added the following observations were made. When 5 ml of sodium hydroxide in methanol were used the color reaction developed represented more than 100 per cent recovery of pregnandiol.

Since the control urines (IV A) indicated that methanolic sodium hydroxide is necessary to remove interfering substances it appeared that 5 ml of sodium hydroxide in methanol might have been inadequate to remove all the nonpregnandiol chromogens. The addition of 10 ml of sodium hydroxide in methanol resulted in pregnandiol recoveries of over 90 per cent. The use of 20 to 30 ml of sodium hydroxide in methanol at step B 3 reduced the pregnandiol recovery. It was possible to recover pregnandiol from the sodium hydroxide precipitates (at step B, 5) of the specimens in which 20 and 30 ml of methanolic sodium hydroxide had been used. It was concluded therefore that 10 ml of 2 per cent sodium hydroxide in absolute methanol would be adequate to remove interfering substances without precipitating pregnandiol prematurely.

1 *Period of Precipitation* — A series of specimens was carried to step C 1. In the original communication¹ it was suggested that aqueous 0.1 N sodium hydroxide be added to the warmed acetone solution to precipitate the pregnandiol. Our quantitative studies indicated that under such conditions the precipitation of pregnandiol reached a maximum after three hours of refrigeration at 5° C. However, it was found that if the sodium hydroxide acetone mixture were boiled three minutes the maximal pregnandiol precipitation occurred in one hour. Extension of the boiling period led to the precipitation of nonpregnandiol chromogens which interfered with the final color reaction.

11 *Color Development With Sulfuric Acid* — The color reactions developed by solutions containing various amounts of crystalline pregnandiol (8.40 and 50 µg) were examined on the colorimeter at frequent intervals starting ten minutes after the addition of the acid. Maximal absorption at 430 mµ occurred

between thirty and sixty minutes later. Since the more concentrated specimens reached their maximal absorption with one hour of development, we employed this standard time interval for reading all our specimens on the spectrophotometer.

VII Standardization Curves—Aliquots of a solution of pregnandiol in absolute alcohol (100 μg per cubic centimeter) were measured from a micro burette into test tubes. The alcohol was evaporated from the tubes in a glycerine bath. After cooling, 5 ml of sulfuric acid (concentrated) were buretted into each tube. The color was allowed to develop for one hour (the tubes being shaken occasionally) and was read on the spectrophotometer at 430 $m\mu$ with concentrated sulfuric acid used as a blank. Fig 3 represents the average results obtained. In the range of 10 to 100 μg per unit volume (5 ml), the concentration is proportional to the log of the per cent absorption, obeying Beer's law. With concentrations greater than 100 μg this relationship does not obtain. A similar standardization curve was obtained when pregnandiol was recovered from pooled female urine to which NaPG had been added in varying amounts.

Fig 3—Standardization curves of the color reaction (with sulfuric acid) of crystalline pregnandiol and pregnandiol recovered from female urine to which NaPG had been added.

The curve is also illustrated in Fig 3. Each point represents the average value of five to ten results. This curve parallels that of pure pregnandiol and indicates that the amount of pregnandiol recovered varies directly with the NaPG present in urine.

To determine the efficiency of the method in recovering pregnandiol from NaPG added to urine, the following calculations were considered:

- 1 Sodium pregnanolone glucuronide constitutes 20 per cent of NaPG.
- 2 The molecular weight of pregnandiol is 320. The molecular weight of pure sodium pregnandiol glucuronide is 536.

Therefore the pregnandiol theoretically obtainable from sodium pregnandiol glucuronide can be calculated from the following equation (where A = weight of NaPG [in mg])

$$\frac{MW \text{ (pregnandiol)}}{MW \text{ (NaPG)}} \times (A - 0.2A) = \text{weight of pregnandiol (in mg)}$$

Table I represents recoveries of pregnandiol from NaPG calculated as indicated. It will be seen that an average of 95 per cent of the theoretic amount available was recovered.

TABLE I RECOVERY OF PREGNANDIOL FROM SODIUM PREGNANDIOL GLUCURONIDE

DISCUSSION

Methods for the quantitative determination of urinary pregnandiol either as the conjugated form, sodium pregnandiol glucuronide or as free pregnandiol have been reported previously.^{3,4,7,10} The majority of the methods require large volumes of urine, consume several days in performance, and usually depend on a gravimetric technique for measuring the final product. The technique reported at this time requires small urine volumes and consists of technically simple manipulations. One person can perform twelve determinations in a working day. The equipment is standard for chemical laboratories and no special apparatus or chemicals are required. The quantitative estimation is a colorimetric procedure which can be adapted to simple laboratory colorimeters. Although the present report considers results obtained with the Cenco Sheard spectrophotometer equally satisfactory results have been obtained in this laboratory with the simpler Klett Summerson photoelectric colorimeter (using Filter 42).

In carrying out this procedure technical difficulties may be prevented if precautions discussed elsewhere are observed.² These simple measures consist of (1) the use of chemically pure reagents, (2) the preparation of fresh 2 per cent sodium hydroxide in absolute methanol every week, (3) the use of air stream in preventing charring of residues at steps B 7 and D 4 and (4) the use of fritted glass filters.

Emulsions have been encountered infrequently at step A, 5. Urine specimens containing large amounts of albumin and/or blood contribute to such emulsion formation. Filtering the visibly bloody specimens reduces the inci-

dence of emulsions. The addition of 1 to 2 drops of a detergent to the toluene mixture usually breaks up the emulsion and facilitates the procedure.

If it is necessary to interrupt the procedure before completion this may be done conveniently at steps B, 2, B, 7 and D, 4.

The observations reported in this paper lead us to conclude that the method proposed permits the determination of pregnandiol alone. Androstosterone (17 ketosteroids) was not found to interfere with the color reaction. The quantitative estimation of pregnandiol in a given urine specimen depends on its spectrophotometric absorption (at $430\text{ m}\mu$). This reading is compared with the standard curve which is a representation of the actual amount of pregnandiol recoverable from urine to which sodium pregnandiol glucuronide has been added.

Failure to use pregnandiol as a standard or to read the color absorption at $430\text{ m}\mu$ has led to results which appear to us to have been interpreted erroneously.^{11, 12} Reinhardt and Barnes¹² utilized 2 per cent potassium dichromate in water (at $420\text{ m}\mu$) as a standard for measuring pregnandiol. Since this solution is fifty times more concentrated than the amount of potassium dichromate equivalent to the pregnandiol standard previously recommended by this laboratory (0.4 mg pregnandiol)² it is not surprising that their results were

Fig. 4—Pregnan diol excretion in normal menstrual cycle (present method)

not consonant with those reported from this laboratory. Others have not only employed potassium dichromate as a standard but have read the colors at higher wave lengths (530 to $570\text{ m}\mu$).¹¹ Since pregnandiol absorption in this region is minimal we feel that the authors were probably measuring substances other than pregnandiol.

The results of quantitative estimations in normal pregnancy in our laboratory are consistent with those obtained by others (Table II). The pattern and levels of pregnandiol excretion in the normal menstrual cycle coincide with

those reported by Venning and Browne¹⁴ (see Fig. 4). These observations, which will be published elsewhere in extenso, further strengthen our conclusion that the method proposed is accurate, specific and practical for research and routine clinical use.

TABLE II. COMPARISON OF PREGNANDIOL EXCRETION VALUES IN NORMAL PREGNANCY

DAY 1	PREGNANDIOL (MC IEP 24 HR.)	PREGNANDIOL (MC IEP 24 HR.)
98.36	5.11	9.16
56.84	6.20	15.38
94.112	10.24	19.36
112.140	13.1	27.46
140.168	22.12	21.62
168.196	44.72	30.72
196.224	48.8	41.81
224.252	55.95	56.108
252.280	60.10	50.10

The two sets of data given in this table are at first glance not strictly comparable. The Venning procedure calculates the pregnandiol concentration from NaPG which contains about 40 per cent of sodium pregnanolone glucuronide. The method here reported estimates pregnandiol only. It would therefore be expected that the pregnandiol values by the Venning method should be about 40 per cent higher than with the present method. The reason for the virtual coincidence of the values remains at present unexplained.

[†]Counted from the first day of the last normal menstrual period.

[‡]From Browne, Henry, and Venning; [§]Venning method (eight cases).

^{||}This laboratory. Present method (four cases).

SUMMARY

A method for the simple quantitative colorimetric determination of urinary pregnandiol is reported.

Spectrophotometric and melting point data are presented as evidence that pregnandiol alone is the substance measured.

Optimal conditions for the quantitative extraction of pregnandiol and color development are established.

Data presented indicate that an average of 95 per cent of the theoretic pregnandiol available is recovered by the procedure reported.

The results of pregnandiol determinations in the menstrual cycle and in normal pregnancy check closely with observations made in other laboratories which employed the longer gravimetric procedure.

We wish to thank Dr. Rachael Levine for his advice and encouragement in this work.

STUDIES IN SERUM PROTEINS

II A RAPID CLINICAL METHOD FOR THE ACCURATE DETERMINATION OF ALBUMIN AND GLOBULIN IN SERUM OR PLASMA

CLARENCE COHN, M.D.,* AND WILLIAM QUITMAN WOLFSON, M.D.†
CHICAGO, ILL.

ELECTROPHORETIC analysis of serum has demonstrated that "serum albumin," as determined by the Howe sodium sulfate method, actually includes both albumin and alpha globulin.^{1,2} Other methods for determining albumin values which approximate those obtained by electrophoresis have certain disadvantages. Precipitation of globulins by methanol as devised by Pillemer and Hutchinson,⁴ is difficult technically since it involves working between 0 and 1° C and, even when these conditions are maintained, occasionally yields erratic results.^{1,2} Popjak and McCarthy's method⁵ for separating albumin and globulin with saturated magnesium sulfate involves a delay of twelve hours before filtration can be carried out. In addition, the albumin in the filtrate cannot be estimated by the biuret reaction but requires a Kjeldahl nitrogen determination. The 28 per cent sodium sulfate method of Milne⁶ also requires an overnight delay for precipitation of the globulins. Chow has reported a quantitative immunochemical reaction which, however, employs biologic material of unstable titer and uncertain composition.

The method described below appears to overcome these difficulties. The procedure is based on our observation that sodium sulfite at a concentration of 26.88 per cent precipitates globulin from serum plasma or plasma fractions. The earlier sodium sulfite method of Campbell and Hanna was adjusted to give results approximating Howe fractions.⁸ Following precipitation of the globulin component immediate filtration yields a solution in which only albumin is found. The albumin in the filtrate may be determined by the biuret reaction of Weichselbaum⁹ or by any other convenient method.

Analyses were performed on human plasma and on subfractions of plasma by the electrophoretic and sodium sulfite methods. The results obtained are compared in Tables I and II.

It will be seen from the results in Table I, obtained on plasma fractions that albumin is not precipitated by 26.88 per cent sodium sulfite to any extent whether in pure solution or combined with mixtures of globulins. All globulins were precipitated regardless of the distribution of globulin subfractions. Although fractions IV 4 and IV 6 contained large amounts of alpha globulin

which by the Howe method is included in the "albumin" fraction, sodium sulfite fractionations give good agreement with electrophoretic values

The human sera analyzed (Table II) consisted of six samples of known electrophoretic composition made available to us* and two of our samples which were analyzed electrophoretically elsewhere†. Mean values for albumin globulin and A/G ratio did not differ from those obtained by electrophoresis by more than 2.2 per cent.

Only one sample of pooled normal serum (Table II) was analyzed both electrophoretically and chemically. However a number of analyses have been carried out on pools of serum obtained from fifty to one hundred fifty donors; these analyses gave an average value of 53 per cent albumin with individual pools varying from 51 to 55 per cent albumin. These values coincide well with the value of 52 per cent albumin obtained for plasma from normal adults by electrophoresis.¹⁰

INTRODUCTION

Reagents —

Twenty eight per cent sodium sulfite solution. Dissolve exactly 28.00 Gm. of anhydrous sodium sulfite in distilled water at 28° C. The salt is difficultly soluble but will go into solution with sufficient shaking. Make up to 100 ml. and store at room temperature.

Buret reagent (Weichselbaum).⁹

Determination —

- 1 Place exactly 24 ml. of sodium sulfite solution in a 25 ml. graduated mixing cylinder. Add 1.0 ml. of serum or plasma and mix well by inversion. Do not shake.
- 2 Filter immediately through a double thickness of folded No. 42 Whatman filter paper. The filtrate should be crystal clear. If the first few drops are turbid they should be refiltered.
- 3 Discard the first 5 ml. of filtrate. (A certain proportion of the albumin in the first few milliliters of filtrate will be adsorbed on the filter paper and low albumin values will be obtained if this material is used for analysis.)
- 4 To 5 ml. of Weichselbaum's buret reagent in a cuvette add 5 ml. of filtrate. Mix well by shaking.
- (The blank is prepared with 5 ml. of buret reagent and 5 ml. of 25 per cent sodium sulfite.)
- 5 After standing thirty minutes the solution is read on a photoelectric colorimeter or spectrophotometer at a wave length of 540 millimicrons.
- 6 The value obtained in the preceding step is that for serum albumin. Globulin is determined as the difference between total protein and albumin values.

*Through the kindness of Dr. Philip P. Cohen of the Department of Physiological Chemistry, University of Wisconsin, Madison, Wis.
†With the cooperation of Mr. Miriam Reiner of the Bloch Medical Laboratory, Mount Sinai Hospital, New York, N. Y.

SUMMARY

A method for the determination of albumin in serum, plasma, or plasma fractions is described. This method gives reproducible results which agree closely with those obtained by electrophoretic analysis. As the procedure is rapid and technically simple, it is suitable for use in the routine clinical laboratory.

We wish to thank Dr Philip P. Cohen of the Department of Physiological Chemistry, University of Wisconsin, Miss Miriam Reiner of the Biochemistry Laboratory, Mount Sinai Hospital, New York, N. Y., Dr A. N. Kutz and Dr J. D. Perrings of the Biochemical Section, The Armour Laboratories, Chicago, Ill., and the members of the Samuel Deutsch Serum Center, Michael Reese Research Foundation, for their cooperation in supplying samples for analysis and providing analyzed samples.

The products of plasma fractionation employed in this work were developed from blood, collected by the American Red Cross, by the Department of Physical Chemistry, Harvard Medical School, Boston, Mass., under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University.

SYSTEMATIC QUALITATIVE ANALYSIS OF BIOLOGIC MATERIALS FOR COMMON STEAM VOLATILE ORGANIC POISONS

ROBERT W. MEALEY, A B, AND ERNEST BUEDELING M D
CLEVELAND, OHIO

TOXICOLOGIC analysis of biologic material is sometimes required when no indication or circumstantial evidence of the presence or absence of a specific poison is available. While adequate systematic qualitative analytic procedures for inorganic poisons such as heavy metals are available, the search for organic poisons necessitates a laborious, time consuming, step by step analysis for each individual compound.

Organic poisons may be divided into the following groups: (1) steam volatile compounds, and (2) nonvolatile compounds extractable with suitable organic solvents from (a) aqueous acid solution and (b) aqueous alkaline solution.

An attempt has been made to develop methods for the systematic detection of various compounds found in each of these groups. In the present paper a simple scheme for the detection of the more common steam volatile poisons is described.

The following compounds are included in the scheme of analysis:

Acid steam distillate: phenol, cresol (triacresol), thymol, aniline, hydrocyanic acid, chloroform, chloral hydrate, carbon tetrachloride, acetaldehyde, ethyl alcohol, formaldehyde, methyl alcohol, nitrobenzene, carbon disulfide.

Alkaline steam distillate: nicotine, amphetamine, aniline.

EXPERIMENTAL

The acid steam distillate is obtained in the following manner. The tissue to be examined (100 Gm.) is homogenized in a Waring blender with distilled water (200 ml.) and the mixture is adjusted with tartaric acid to a pH of 5.0. The homogenate is transferred to a distilling flask (1 liter) which is part of an all glass steam distilling apparatus*. About 5 Hengar boiling granules are added to the steam generating flask. All joints are lubricated with a thin layer of silicone. The distillate is collected in a suitable cooled container with the end of the condenser immersed in distilled water (10 ml.). The steam distillation is carried out until 200 ml. have been collected.

The homogenate is then made alkaline with magnesium oxide to a pH of 8.0. The steam distillation is repeated and 200 ml. of distillate again are collected.

From the Department of Pharmacology, School of Medicine, Western Reserve University. Supported in part by special gifts from Mrs. S. Prentiss Baldwin.
Received for publication Dec. 23, 1947.
The apparatus designed for this procedure according to our specifications was obtained from E. Machlett & Sons, New York, N. Y.

Quantities of tissue weighing less than 100 Gm may be analyzed by employing proportionately smaller volumes of water in preparing the homogenate and by collecting appropriately reduced volumes of distillate. However, a minimum of 25 Gm of tissue is recommended for a complete analysis.

In the literature of this subject are described a large number of tests for the detection of the poisons considered in this scheme. However, many of these tests proved to be unsatisfactory, either because of insufficient sensitivity or because they gave positive or equivocal results with steam distillates from tissues containing no poison. Since each of those tests which was found suitable has been modified, a detailed description of each procedure is given. Reference is made to the papers in which the tests were originally described. The lowest concentration of the compound at which the test is definitely positive is listed. This concentration is considered the practical limit of sensitivity. None of the tests described give positive results with steam distillates from homogenates of liver containing no poison.

1 *Precipitation Test With Bromine Water*¹—To the distillate (1 ml) add bromine water (1 drop). If no precipitation occurs, add additional reagent (2 or more drops). A positive reaction is indicated by the formation of a white or yellowish precipitate or by a definite cloudiness of the solution.

Sensitivity Phenol, 0.0025 per cent, cresol, 0.0020 per cent, thymol, 0.0015 per cent, aniline, 0.0015 per cent.

2 *Millon's Test*²—To the unknown solution (3 ml) in a small test tube add the reagent (3 drops). Heat the mixture at first gently, then with a gradually increasing intensity while observing carefully for changes in color. A positive reaction is indicated by a red or red-brown color or a precipitate. A bright yellow precipitate may form, this may consist of mercury salts and does not indicate a positive test.

Sensitivity Phenol, 0.0007 per cent, cresol, 0.0007 per cent, aniline, 0.0050 per cent.

3 *Prussian Blue Test for Cyanide*^{3, 4}—To the unknown (3 ml) in a test tube add a solution of potassium hydroxide (5 per cent, 3 or 4 drops), then a freshly prepared solution of ferrous sulfate (2 per cent, 1 or 2 drops), and a solution of ferric chloride (1 per cent, 1 drop). Shake the solution and warm gently. Acidify carefully with hydrochloric acid (2N). If much hydrocyanic acid is present a precipitate of prussian blue (ferric ferrocyanide) will appear at once, but if the concentration is weak the colloidal solution will have merely a blue, blue green, or green-blue color. After some time a flocculent precipitate of prussian blue will settle to the bottom of the tube. Prussian blue will not appear if the reaction is alkaline. On the other hand, in strongly acid solutions the formation of prussian blue is delayed. Therefore, the final mixture should be adjusted (with indicator paper) to the optimal range of pH 2 to pH 5.

The limiting concentration of hydrocyanic acid in this test has been stated to be 1:50,000 (0.002 per cent)³, for practical purposes, however, the sensitivity is limited to a concentration of 0.004 per cent.

4 *Alkaline Pyridine Test* —To the unknown solution (2 ml) in a medium sized test tube add pyridine (0.4 ml 10 per cent grade) and mix thoroughly. Add a solution of potassium hydroxide (40 per cent 4 ml) and heat one to three minutes in a boiling water bath while observing the pyridine layer for color changes. A red color developing in the pyridine layer within three minutes signifies a positive test. The color may fade with continued heating and it is essential therefore, to observe the reaction carefully.

Sensitivity Chloroform, 0.0002 per cent chloral hydrate 0.0001 per cent carbon tetrachloride, 0.025 per cent

5 *Direct p Hydroxydiphenyl Test* ^{12b}—To the distillate (1 drop) add a solution of copper sulfate (1 per cent 1 drop) and then concentrated sulfuric acid (1 ml). Immediately cool the tube with ice water and add a drop of the p hydroxydiphenyl reagent (p hydroxydiphenyl 1.5 per cent in a solution of sodium hydroxide 0.5 per cent). Shake the mixture thoroughly and allow it to stand for twenty minutes.

A blue color is formed in the presence of acetaldehyde; this changes gradually to bright violet (maximal color intensity occurs after twenty to thirty minutes) with formaldehyde a bright green color is produced but this changes to blue on standing.

Sensitivity Formaldehyde 0.0002 per cent acetaldehyde 0.0008 per cent

6 *p Hydroxydiphenyl Test Following Oxidation* ¹²—In a large test tube place the distillate (0.1 ml) a solution of potassium permanganate (5 per cent 1 drop) and phosphoric acid (10 per cent 1 drop). After mixing the solution is allowed to stand at room temperature for one minute. Add a solution of oxalic acid (saturated) drop by drop, with shaking until the solution is decolorized. After decolorization has occurred add concentrated sulfuric acid (6 drops) while agitating the tube in ice water. Remove the tube from the bath add a solution of copper sulfate (1 per cent 1 drop) and mix. Replace the tube in ice water and agitate it while adding concentrated sulfuric acid (3 ml). Remove the tube from the bath, add a drop of the p hydroxydiphenyl solution (as in Test 5), mix well and allow to stand at room temperature. Record any production of color after twenty to twenty five minutes.

In the presence of methyl alcohol a bright green blue to blue color is produced while with ethyl alcohol a bright blue violet color appears.

Sensitivity Methanol, 0.0008 per cent ethanol 0.004 per cent

7 *Indophenol Test* —To the unknown solution (3 ml) slowly add concentrated H_2SO_4 (3 ml) while cooling the tube in a beaker of water. Then add a small amount of sodium nitrite and mix. Allow to stand at room temperature for five minutes and observe the color.

In the presence of phenol in a concentration of 0.01 per cent or higher a red color is produced. In a still higher concentration (1:1000) other phenols also produce colors: cresol yellow brown thymol faint yellow.

8 *Ware's Test for Phenol*—To a portion of the distillate (1 ml) add concentrated HCl (3 ml). Mix and warm in a water bath at 70° C for one minute. Quickly add a small amount of Ware's mixture (sodium nitrite, 1 part, sodium nitrate, 1 part, anhydrous sodium sulfate, 2 parts) and let stand at room temperature for five minutes. Observe the color. Cool, make alkaline with a concentrated solution of NH_4OH , and again observe the color.

In the presence of phenol a cherry red color is produced in acid solution and a green color in alkaline solution. The test is sensitive to at least 1 ml of 0.02 per cent phenol. Thierisol and aniline produce yellow or brown colors, but these are readily distinguished from the colors observed in the presence of phenol.

9 *Selenous Acid Test*⁹—To a portion of freshly prepared Mecke's reagent (25 ml) add the distillate (0.5 ml). Mix and observe the color at once (Mecke's reagent is prepared by dissolving 0.5 Gm of selenous acid in 100 ml of concentrated sulfamic acid).

In the presence of thierisol a distinct red color is produced, whereas phenol is at first yellow green and gradually becomes red-brown.

Sensitivity Thierisol 0.005 per cent.

10 *Hypochlorite test*¹⁰—To the distillate (5 drops), in a depression of a white spot plate add chemically pure aqueous sodium hypochlorite solution (2 drops) and observe any change in color.

If aniline is present in concentrations greater than 0.0025 per cent, a clear violet, gradually changing to a dirty violet color, is produced.

11 *Diazotization and Coupling*¹¹—The distillate (1 drop), in a depression of a white spot plate is acidified with dilute HCl (1 small drop). Add a freshly prepared solution of sodium nitrite (0.2 per cent, 1 drop) and mix. Destroy the excess nitrous acid with a solution of ammonium sulfamate (1 per cent, 1 drop). Then add freshly prepared coupling reagent, N-(1-naphthyl) ethylene diamine dihydrochloride (0.2 per cent, 1 drop), and observe the development of color during a period of one to two minutes.

Aniline (and all other primary amines) form diazo compounds with nitrous acid, these are converted to highly colored azo compounds with N-(1-naphthyl)-ethylenediamine. With aniline a purple color is produced which becomes gradually more intense within about one minute after addition of the coupling agent. Phenol, cresol, amphetamine, and nicotine are negative. The test is sensitive to 0.00065 per cent aniline.

12 *Test With Wasicky's reagent*¹²—To the distillate (1 ml) add quickly, with mixing, an equal volume of the reagent (β -dimethylaminobenzaldehyde, 2 Gm, in concentrated H_2SO_4 , 6 ml, to which water, 0.4 ml, is added). Observe the color immediately.

In the presence of thymol an orange to orange-red color is produced whereas the control (distilled water) tested in the same manner has a pale yellow color.

The test is positive to 0.001 per cent thymol. The orange color fades quickly.

13 *Fulton's Test for Phenols*¹³—To the distillate (5 ml) add NH_4OH (28 per cent, 5 drops) hydrogen peroxide (3 per cent 1 ml), and a solution of copper sulfate (0.1 per cent, 3 drops). Mix and let stand for ten minutes. In the presence of thymol a pink violet color is produced.

This test is not very sensitive. The absolute limit of sensitivity is a thymol concentration of 0.005 per cent. Other phenols also produce colors; for example, a solution of tricresol produces an orange pink color which changes to yellow.

14 *Thiocyanate Test*¹⁴—To the distillate (3 ml) in a test tube add KOH (2N, 1 drop) and a solution of yellow ammonium sulfide (a solution of 10 per cent ammonium hydroxide saturated with hydrogen sulfide 2 drops). Heat gently for two minutes over the flame and add HCl (4N, 0.5 ml). Allow the solution to cool, add a solution of ferric chloride (1 per cent, 3 to 5 drops). A red or red brown color indicates the presence of cyanide.

The test is sensitive to 3 ml of a 1:70,000 solution of cyanide (calculated as HCN).

15 *Picric Acid Test*¹—To the distillate (3 ml) add a solution of picric acid (saturated, 3 drops) and a solution of sodium carbonate (20 per cent, 3 drops). Warm gently over the flame for a few minutes, allow to stand at room temperature for ten minutes. An orange red color or precipitate indicates a positive test.

The test is sensitive to 3 ml of a 1:250,000 cyanide solution (calculated as HCN).

16 *Resorcinol Test (Strong Alkali)*¹⁶—To the distillate (1 ml) add aqueous resorcinol solution (saturated 2 drops) and a solution of KOH (20 per cent, 1 ml). Warm at 60°C in a water bath for two to three minutes and observe the color of the solution. A red color is produced with chloroform, chloral hydrate, and carbon tetrachloride.

Sensitivity Chloroform, 0.005 per cent; chloral hydrate, 0.002 per cent; carbon tetrachloride, 0.025 per cent.

17 *Resorcinol Test (Weak Alkali)*¹⁶—To the distillate (1 ml) add resorcinol solution (saturated 2 drops) and a solution of sodium carbonate (20 per cent, 1 ml). Shake and let stand for twenty minutes at room temperature. Dilute with distilled water (2 or 3 volumes) and observe the tube for green fluorescence. Viewing conditions must be optimal or the fluorescence may be missed. View against a black background with light directed toward the tube at an angle of 90° degrees from the line of vision.

A solution of chloral hydrate in a concentration of 0.001 per cent is sufficient to give a positive test, whereas chloroform and carbon tetrachloride are negative.

18 *Phloroglucinol Test*¹—To the distillate (1 ml) add a small amount of granular phloroglucinol (chemically pure) and a solution of sodium carbonate (20 per cent, 1 ml). Shake and observe the color during a period of one half hour at room temperature.

A solution containing as little as 0.001 per cent chloral hydrate will produce an orange-red color. The color of the control is pale-violet. Chloroform and carbon tetrachloride do not give this test.

19 *Chromotropic Acid Test*^{18a} (According to Feigl^{18b})—The distillate (0.05 ml or 1 drop), in a test tube, is mixed with a solution of sulfuric acid (72 per cent, 3 ml). A little solid chromotropic acid (1,8-dihydroxy naphthalene 3,6-disulfonic acid) is added and the tube is heated in a water bath at 60° C for ten minutes. A bright violet color appears in the presence of formaldehyde. The test will detect formaldehyde in a 0.0007 per cent solution. Acetaldehyde is negative.

20 *Fuchsin Test*^{18b, 19}—To the distillate (1 ml) add reduced fuchsin reagent (10 drops) and concentrated H_2SO_4 (5 drops). Let stand at room temperature for twenty minutes. The presence of formaldehyde is indicated by a violet color.

Sensitivity Formaldehyde, 0.001 per cent, acetaldehyde is negative.

The reagent is prepared as follows. Dissolve basic fuchsin (2 Gm) in hot water (120 ml) and allow the solution to cool. Add a solution of sodium sulfate (2 Gm) in distilled water (20 ml) and follow with concentrated HCl (2 ml). Dilute with distilled water to 200 ml and let stand at least one hour. The freshly prepared solution has a yellow color and should be stored in a cold room.

21 *Oxidation Tests for Methanol*^{18b, 19}—To the distillate (5 ml) add a solution of potassium permanganate (5 per cent, 3 drops) and a solution of phosphoric acid (10 per cent, 4 drops). Let stand at room temperature for two minutes. Add small amounts of sodium bisulfite, with mixing, until the solution is decolorized (avoid excessive quantities).

Divide the solution in two parts

(a) To the oxidized solution (3 ml) add reduced fuchsin reagent (15 drops) and concentrated H_2SO_4 (6 drops). Mix and let stand for twenty minutes. If methanol is present in the original solution in a concentration of 0.008 per cent or higher a violet color will appear.

(b) To the oxidized solution (1 ml) add H_2SO_4 (72 per cent, 4 ml) and a small amount of chromotropic acid. Warm at 60° C for ten minutes (see Test 19).

Sensitivity Methanol, 0.0013 per cent.

22 *Electrolytic Reduction of Nitrobenzene and Detection of the Nitroso Compound Produced*^{18b, 20}—To the distillate (1 ml) in a small (10 ml) beaker add the freshly prepared reagent (1 per cent solution of sodium pentacyanoamine ferriate, 1 ml)²¹ and a solution of sodium hydroxide (4N, 1 ml). A current is then allowed to pass through the solution using a nickel wire as a cathode and a lead wire as an anode. The source of the current can be either a flashlight battery or a 4-volt storage battery. Allow the electrolysis to proceed for one-half hour. If nitro compounds are present in the original solution

a color will appear during the electrolysis nitrobenzene producing a bright green color varying in intensity with the concentration. With high concentrations a dark violet color may be produced.

Sensitivity Nitrobenzene, 0.006 per cent

23 *Reduction-Diazotization Test*¹¹—To the distillate (6 drops) in a test tube add HCl (2N, 3 drops) and a small amount of zinc powder. Agitate and allow to stand for two to three minutes at room temperature. Remove two drops with a dropper and place them in a depression of a white spot plate, then perform the diazotization test (Test 11).

In this test nitrobenzene is reduced to aniline which is detected by diazotization and coupling. The test is sensitive to a solution of 0.006 per cent nitrobenzene.

24 *Formaldehyde Plumbite Test*^{12b, 2}—To the distillate (2 ml) add bromine water, drop by drop, until the light yellow color is permanent. Let stand for two minutes. In this way hydrogen sulfide which interferes with the test, is removed by oxidation. Remove the excess bromine by adding a small amount of sodium sulfite. Then add formaldehyde (40 per cent, 5 drops) and alkaline plumbite solution (5 drops). (Prepare the solution by dissolving lead acetate 1 Gm, in water 100 ml, and adding KOH 20 per cent until the precipitate which forms has dissolved.) Let stand for one half hour. If large amounts of carbon disulfide are present a black or dark brown precipitate will form while with smaller amounts the solution is colored yellow brown.

Sensitivity Carbon disulfide, 0.004 per cent

25 *Ammonium Molybdate Test*^{2, 1b}—To the distillate (2 ml) add alcoholic potassium hydroxide (10 per cent, 0.5 ml) and heat in a boiling water bath for five minutes. Cool to room temperature then add ammonium molybdate solution (2 drops) and acidify with concentrated sulfuric acid added drop by drop. In the presence of carbon disulfide a blue or green blue color develops which, with very small amounts of carbon disulfide, may form only very slowly. Therefore, allow the tube to stand for two hours at room temperature. A greenish yellow color may develop in the distilled water control.

Sensitivity Carbon disulfide, 0.004 per cent

26 *Precipitation With Nessler's Reagent*³—To the distillate from the alkaline solution (5 ml) add Nessler's reagent (10 drops). If a precipitate does not appear at once, prick the tube in ice or keep in the refrigerator for at least four hours and again examine for a precipitate.

In a concentration of 0.1 per cent, amphetamine produces an amorphous white precipitate. In a concentration of 0.02 per cent a white cloud appears. Aniline and nicotine are not precipitated even at concentrations higher than 0.1 per cent.

27 *p-Nitroaniline Test*⁴—The alkaline distillate (15 ml) is extracted with three portions (5 ml each) of a mixture of petroleum ether toluene (1:1) by shaking for five minutes with each extraction. The amine is transferred to

aqueous solution by washing the combined ether-toluene fractions with two portions of HCl (0.2 per cent, 5 ml each). The acid solution is carefully adjusted to pH 6 to pH 7 with dilute NaOH solution. To the resulting solution (5 ml) add cold p-nitrobenzenediazonium chloride reagent (5 ml) and allow to stand for an hour at room temperature. Add a solution of sodium carbonate (11 per cent, 5 ml), let stand for fifteen minutes, and add sodium hydroxide (10 per cent, 1 ml) to develop the color.

In the presence of amphetamine a distinct red color is produced. Aniline may also produce a red color even when very small amounts are present. Nicotine, however, is negative to this test or may produce a nondescript greenish yellow color. A solution of 0.001 per cent amphetamine (sulfate) may be detected.

Stock-Solution p-Nitroaniline (3.5 Gm) is suspended in concentrated HCl (5 ml) by breaking up clumps with a glass rod. The suspension is diluted with distilled water to 500 ml, shaken for twenty minutes, and filtered. The filtrate remains stable when kept in the refrigerator.

TABLE I. GROUP REACTIONS FOR POISONS IN THE ACID STEAM DISTILLATE

Group I—Positive to bromine water test (1)		Group II—Negative to bromine water test (1)	
Aniline	Cresol (Tricresol)	Hydrocyanic acid	Formaldehyde
Phenol	Thymol	Chloroform	Nitrobenzene
Millon's test (2)		Carbon tetrachloride	Methyl alcohol
		Chloral hydrate	Carbon disulfide
		Acetaldehyde	
		Ethyl alcohol	
Positive	Negative	Prussian blue test (3)	
Group I A	Group I B	Positive—Group II A	Negative—Group II B
Aniline	Thymol	Hydrocyanic acid	All others
Phenol			Direct alkaline pyridine test (4)
Cresol			
		Positive—Group II B 1	Negative—Group II B 2
		Chloroform	Acetaldehyde
		Chloral hydrate	Ethyl alcohol
		Carbon tetrachloride	Formaldehyde
		(in concentration of 1:5,000 or higher)	Methyl alcohol
			Nitrobenzene
			Carbon disulfide
		Direct p hydroxydiphenyl test (5)	
		Positive—Group II B 2a	Negative—Group II B 2b
Acetaldehyde		p Hydroxydiphenyl test following oxidation (6)	
Formaldehyde		Positive—Group II B 2b 1	Negative—Group II B 2b 2
		Methyl alcohol	Nitrobenzene
		Ethyl alcohol	Carbon disulfide

Reagent The stock solution (10 ml) is cooled (0°C), concentrated HCl (2 ml) is added and the mixture is allowed to stand at 0°C for ten minutes. Freshly prepared sodium nitrite solution (0.7 per cent, 6 ml) is added, and after another ten minutes at 0°C the solution is diluted with distilled water to 200 milliliters. The solution is ready for use after it has remained at 0°C for two hours. When stored in a cold room it remains stable for three weeks.

28 Picric Acid Precipitation Test²—To the distillate (5 ml) add picric acid solution (saturated, 10 drops) and mix. Allow to stand in ice or in the refrigerator for four to six hours. If a precipitate forms, examine it under the microscope.

If nicotine is present characteristic crystals of the picrate will appear. These are long thin, yellow needles which grow in fan shaped clusters resembling sheaves of grain.

Sensitivity Nicotine, 0.0025 per cent.

Aniline and amphetamine in much higher concentrations may be precipitated by picric acid but the precipitate is not characteristic in appearance.

29 Oxidation Nitroprusside Test^{2c}—To the distillate (5 ml) add 2 drops of a buffer solution of pH 4.0 (72 ml of molar acetic acid, 12 ml of molar sodium hydroxide), potassium persulfate (0.1 to 2 Gm) and a solution of silver nitrate (1 per cent, 1 drop). Place in a boiling water bath for one minute, shake well and cool at 20°C . Add crystalline sodium thiosulfate (0.05 to 0.15 Gm) shake until dissolved, add sodium nitroprusside (10 per cent 2 to 4 drops), and make slightly alkaline with ammonium hydroxide solution (3 per cent).

In the presence of nicotine a red color appears in two to three minutes. The solution must be slightly acid and must be free from ions which precipitate silver ions. The presence of aniline produces a violet discoloration during the heating but the color soon changes to yellow. With larger amounts of aniline the solution becomes black and interferes with the test. Amphetamine does not produce a color.

Sensitivity Nicotine, 0.0025 per cent.

DETECTION OF POISONS IN THE ACID AND ALKALINE STEAM DISTILLATES

In Table I the poisons in the acid steam distillate are classified according to group reactions. (The figures in parentheses refer to the number under which the test is described in the preceding section of this paper.) After a poison has been classified by the group reaction its presence is ascertained by further differentiating and confirmatory tests (Table II).

DISCUSSION

Phenolic compounds such as salicylic acid, α and β naphthol and p-cresol are not included in this scheme since in disagreement with certain text books of toxicology² it was found that these compounds are not steam volatile to any significant degree even if the pH of the solution to be distilled is as low as 2.0.

TABLE II DIFFERENTIATING TESTS—ACID STEAM DISTILLATE

Group I A						
	INDOPHENOL TEST (7)	WARE'S TEST (8)		SELENOUS ACID TEST (9)	HYPOCHLORITE TEST (10)	DIAZOTIZATION AND COUPLING (11)
		ACID SOLUTION	ALKALINE SOLUTION			
Phenol	Red, Red brown	Cherry red	Green	Pale yellow	Neg	Neg
Tricresol	Light brown	Dark amber	Yellow	Red amber	Neg	Neg
Aniline	Pale yellow or colorless	Yellow	Bright yellow	Pale yellow	Violet	Bright purple
Group I B						
Thymol	Test with Wasicky's reagent (12)—orange red color					
Fulton's test for phenols	(13)—pink violet color					
Group II A						
Hydrocyanic acid						
Thiocyanate test (14)	—red or red brown color					
Picric acid test (15)	—orange red color or precipitate					
Group II B 1						
	RESORCINOL TEST (16) STRONG ALKALI	RESORCINOL TEST (17) WEAK ALKALI	PHLOROGLUCINOL TEST (18)			
Chloral hydrate	Bright red	Green fluorescence	Lilac, changing to orange, to red			
Chloroform	Red, orange red	No fluorescence	Neg			
Carbon tetrachloride	Red, orange red	No fluorescence	Neg			
Group II B 2a						
	CHROMOTROPIC ACID TEST (19)			FUCHSIN TEST (20)		
Acetaldehyde	Neg			Neg		
Formaldehyde	Pos			Pos		
Group II B 2b 1						
	OXIDATION (21) FOLLOWED BY CHROMOTROPIC ACID TEST (19)			FUCHSIN TEST (20)		
Methyl alcohol	Pos			Pos		
Ethyl alcohol	Neg			Neg		
Group II B 2b 2						
	ELECTROLYTIC REDUCTION (22)	REDUCTION DIAZOTIZATION (23)	FORMALDEHYDE PLUMBITE TEST (24)	AMMONIUM MOLYBDATE TEST (25)		
Nitrobenzene	Green color	Pos	Neg	Neg		
Carbon disulfide	Neg, yellow color of reagent	Neg	Yellow, brown, or black precipitate or solution	Blue or blue green color		

TABLE III DIFFERENTIATING TESTS—ALKALINE STEAM DISTILLATE

	NESSLER'S TEST (26)	P NITRO ANILINE TEST (27)	PICRIC ACID TEST (28)	OXIDATION NITROPRUS SIDE TEST (29)	DIAZOTIZATION AND COUPLING (11)	HYPOCHLORITE TEST (10)
Amphetamine	Pos	Pos	Amorphous or no precipitate	Neg	Neg	Neg
Nicotine	Neg	Neg	Characteristic needle shaped crystals	red color	Neg	Neg
Aniline	Neg	Pos	Amorphous or no precipitate	Neg or black	Pos	Pos

Tests for the presence of aniline should be carried out in both the acid and alkaline steam distillates since this compound is steam volatile at both pH 5.0 and pH 8.0

Carbon tetrachloride is positive to the tests listed for chloroform, but only in much higher concentrations. Therefore, if these tests are positive, the possibility of the presence of carbon tetrachloride should be kept in mind. However, if the steam distillate is positive to these tests and does not have the odor of carbon tetrachloride, it is likely to contain chloroform.

Acetone is not included in the scheme. Since ketone bodies are normal intermediaries of fat metabolism, steam distillates of homogenates from tissues (such as liver and kidney) regularly give positive reactions if sensitive tests for acetone are performed.

SUMMARY

An analytic scheme for the detection of the more common steam volatile organic poisons is described.

A METHOD FOR THE DETERMINATION OF TITERS BETWEEN 10 AND 100 IN THE QUANTITATIVE COMPLEMENT FIXATION TEST FOR SYPHILIS

ELIZABETH MALTNER B S AND GLADYS M GAMESH B S
ALBANY N Y

THE value of quantitative tests in diagnosis and control of treatment of syphilis is now widely appreciated. The complement fixation test developed in this laboratory is based on essential quantitative principles^{1,2} and in practice yields an accurate and reproducible index of titer.^{10,14} Studies have long been directed to a simplification of the method that would not sacrifice the advantages of an optimally adjusted system. The present report describes an abbreviated technique in which four or six dilutions of the specimen are titrated with six 50 per cent units of complement. The final values are read directly from tables. The method is well suited to the testing of sera from patients under treatment for primary or secondary syphilis and indeed for all but an occasional specimen.

The rationale and technique for determining titers greater than 10 in the quantitative complement fixation test for syphilis have been described in previous publications.¹⁻¹⁶ The procedure¹ first used employed a graphic expression of the results, on the basis of which titers were determined by linear extrapolation. This method required testing several dilutions of a specimen with varying amounts of antigen and 3, 6, 9 and 12 units of complement and was applicable to specimens of all degrees of reactivity. Titers from slightly over 10 that is 11 or 12 to titers of 300 to 500 and even up to 2,000 were obtained. A procedure in which 6 and 9 units of complement were used each with a single amount of antigen was later found to simplify the technique considerably without great sacrifice of accuracy.^{16,17} The graphic method of estimating titers was supplanted by tables of calculated values. Experience with this method in testing sera from patients under treatment for primary and secondary syphilis indicated that titers up to 100 furnish as much information as is required in the management of such cases. The procedure here described was designed primarily to determine titers in the range of 10 to 100. It can nevertheless be extended readily to determine higher titers.

A preliminary titer range test is performed to select the amounts of serum to be tested.

Technique of the Titer Range Test for Use With Serum—The technique of the titer range test differs slightly from the one previously described.¹⁶ Proceed as indicated in Table I. Prepare the 1:5 dilution of the reacting serum to be tested using as a diluent pooled human sera that are clear and colorless, are not anticomplementary and have failed to react in serologic tests for syphilis. Use

From the Division of Laboratories and Research, New York State Department of Health.
Received for publication Dec. 1, 1947.

this diluent also to adjust the volume of serum to 0.05 ml in tube 2. Inactivate the diluent for thirty minutes each day before use. Controls of the anticomplementary activity of the specimen are included in Table I but are not essential. They are of value in estimating the approximate titer.

TABLE I. PRELIMINARY TITER RANGE TEST OF SERUM

TUBE	REACTING SERUM		EQUIVALENT AMOUNT OF SERUM (ML)	POOLED NON REACTING SERA (ML)	CARDIO LIPIN ANTIGEN #72 DILUTED 1:67 (ML)	UNITS OF COMPLEMENT PER 0.1 ML (ML)		SALT SOLUTION (ML)	PERIOD OF FIXATION	SENSITIZED SHEEP CELLS (ML)	PERCENT HEMOLYSIS
	DILUTION	AMOUNT PIPETTED (ML)				1	6				
1	1:5	0.05	0.01		0.1		0.1	0.05	4 hr, 36°C	0.2	100% CL
2	1:5	0.02	0.004	0.03	0.1		0.1	0.05		0.2	
3	Undiluted	0.05	0.05			0.1		0.15		0.2	
4	Undiluted	0.05	0.05			0.2		0.05		0.2	

Tubes 3 and 4 can be omitted if an estimated titer is not desired.

The titer is expressed as the ratio of the amount of complement required to give 50 per cent hemolysis with 0.05 ml of serum (or 0.2 ml of cerebrospinal fluid) and an optimal dose of antigen to the amount required to give 50 per cent hemolysis with the same amounts of the specimen alone. For convenience, the findings with specimen and antigen are referred to as (S+A) and with the specimen alone, as (S). The titer is the ratio $\frac{(S+A)}{(S)}$, and is expressed in two significant figures. Record the percentage of hemolysis in each tube by comparison with a color standard.¹⁶¹ Determine the values of (S+A) by reference to Table II.

TABLE II. VALUES OF (S+A)* FOR TESTS WITH 6 UNITS OF COMPLEMENT, ANTIGEN, AND DILUTED SERUM

PER CENT HEMOLYSIS	SERUM DILUTED TO 1

70	14	16	22	27	32	41	51	68	81	100
75	13	16	21	26	31	39	49	65	78	95
80	12	15	20	25	29	37	47	61	74	94
85	12	14	19	24	28	35	45	59	71	94
90	11	13	18	22	26	33	42	55	66	85
95	10	12	16	20	24	30	38	50	60	80

* (S+A). The units of complement required for 50 per cent hemolysis with specimen and antigen (Table IX, line 4) multiplied by the dilution factor.

Interpretation of the Titer Range Test With Serum—When complete hemolysis is obtained with both amounts of serum tested, the value for (S+A) is less than 20, and amounts from 0.02 through 0.01 ml should be tested to determine the exact titer (see Table II). Five hundredths of a milliliter of serum diluted from 1:2.5 through 1:5 are used in the test.

When partial hemolysis is obtained with either amount in the titer range test, determine from Table II the amounts of serum and the sequence of dilutions to use, for example, if 10 per cent hemolysis occurs with 0.01 ml and complete hemolysis with 0.004 ml, a value between 42 and 50 is indicated. Therefore, test the serum diluted from 1:4 through 1:12.5. These dilutions include one amount above and one below the range of values indicated for (S+A) to allow for possible variations in complement.

When no hemolysis is obtained in either amount in the titer range test, the value of (S+A) is greater than 100. If the exact titer is desired in such instances titrate amounts smaller than 0.004 milliliter. For this purpose, use a series of dilutions ten times as great as those given in Table II.

Table III indicates the amounts of reacting and nonreacting serum used to prepare the dilutions.

TABLE III AMOUNTS OF REACTING AND NONREACTING SERUM USED IN THE PREPARATION OF DILUTIONS

DILUTION	REACTING SERUM (ML)	NONREACTING SERUM (ML)	REACTING SERUM CONTAINED IN 0.05 ML OF EACH DILUTION (ML)	REMARKS
1:2.5	0.08	0.12	0.02	Higher dilutions in

1:4	0.05	0.15	0.0125	sion can be pre-
1:5	0.05	0.2	0.01	pared for determin-
1:6	0.04	0.2	0.0083	ing titers greater
1:7.5	0.04	0.26	0.0067	than 100. Do not
1:9.5	0.02	0.17	0.0053	pipette less than
1:12.5	0.02	0.23	0.004	0.02 ml of reacting
1:15	0.02	0.28	0.0033	serum to prepare
1:20	0.02	0.38	0.0025	dilutions for these tests

Technique of the Titer Range Test for Use With Cerebrospinal Fluid—When the titer of the cerebrospinal fluid is greater than 10, perform a titer range test as outlined in Table IV. Use Table V for determining the value of (S+A). Depending upon the range of reaction indicated by this test, use in the final titration, varying amounts of a 1:2 dilution made with salt solution in the sequence of amounts given in Table V. If titers greater than 100 are desired use a 1:20 dilution.

Technique for Determination of Titers Between 10 and 100 for Both Serum and Cerebrospinal Fluid—The method of testing is illustrated in Tables VI and VII, and typical results are shown in Table VIII. The calculated values for (S+A) corresponding to the degrees of hemolysis obtained in the test of the different amounts of the specimen used are shown in Tables II and V. These

2nd dilution	0.05	0.1		0.1	0.05		0.2	
3rd dilution	0.05	0.1		0.1	0.05		0.2	
4th dilution	0.05	0.1		0.1	0.05		0.2	
5th dilution	0.05	0.1		0.1	0.05		0.2	
6th dilution	0.05	0.1		0.1	0.05		0.2	

values were obtained by multiplying the units of complement required for 50 per cent hemolysis in the presence of the diluted specimen and the maximum reacting dose of antigen, as read from line 4 of Table IX, by the dilution factor,

that is, 0.05 ml divided by the milliliters of serum used. For example in a test in which 65 per cent hemolysis occurs with 0.05 ml of a 1:5 dilution of serum, (S+A) would be $5.4 \times \frac{0.05}{0.01}$ or 27. Similarly in a test of 0.02 ml of cerebrospinal fluid 40 per cent hemolysis would correspond to an (S+A) value of $6.4 \times \frac{0.2}{0.02}$, or 64.

The 50 per cent unit values of the reactions in the controls of the specimen without antigen are also read from Table IX. Determine the titer by dividing the maximum value for (S+A), Table II or V by the maximum value for (S) Table IX. Consider specimens anticomplementary if the reaction without antigen is 20 or greater. Anticomplementary reactions can be measured, but since it is doubtful how much this property of serum or cerebrospinal fluid affects the fixation due to syphilitic reagent the titers obtained with anticomplementary specimens must be considered approximate values only. Always include controls (S) with sufficient complement to produce partial degrees of hemolysis in tests of anticomplementary specimens. Whenever the value of (S) is less than 1 the value of (S+A) represents the titer of the specimen that is a value of less than 1 is never used in the denominator of the fraction $\frac{(S+A)}{(S)}$.

Evaluation of Results—Compare the maximum reaction obtained with serum and antigen in the final titration with that obtained in the titer range

test. Determine the relative discrepancy either by dividing the difference of the two results by the mean or by comparing them with the pairs of numbers listed in Table X. Repeat the examination of specimens if the findings show more than 25 per cent relative discrepancy. If controls without antigen have been included in the titer range test comparison of the ratios, $\frac{(S+A)}{(S)}$, rather than of the values, (S+A) usually shows closer agreement and less repetition is required.

DISCUSSION

In routine practice in this laboratory about 85 per cent of specimens received for serologic tests for syphilis can be reported as not reacting on the basis of two preliminary tests—one of complement fixation^{16b} and the other of precipitation^{16c}, both tests are oversensitive and require one tube each. The remaining reacting sera are tested in the six-tube quantitative procedure,^{16d} in which titers up to 10 are determined. Specimens having titers greater than 10—about half of those examined quantitatively—are then tested in a two tube titer range test, which indicates the dilutions to be used in determining the exact titer. The successive tests reduce to a minimum the number of specimens requiring titration in dilution and some advantage is derived from the confirmatory evidence they afford.

Studies are being continued to modify the technique of the six tube quantitative test to extend the range of determinable titer somewhat beyond 10. It is hoped that this will largely eliminate, or permit better interpretation of, the so called atypical reaction in these lower ranges and also avoid the inaccurate index of titer occasionally encountered in the tube containing 12 units of complement which now requires a supplementary test to correct. Possibly a greater flexibility of procedure will be provided also.

SUMMARY

A simplified technique for determining titers between 10 and 100 in the quantitative complement fixation test for syphilis is described. Two amounts of serum or cerebrospinal fluid are tested to determine the range of reactivity and from four to six dilutions are tested to determine the exact titer. Although the method is designed primarily for determination of titers under 100, it is also applicable to determinations of higher titers.

The procedure results in material saving of time and reagents as compared with previous methods.

THE PREPARATION OF FROZEN SECTIONS FOR USE IN THE CHEMOSURGICAL TECHNIQUE FOR THE MICROSCOPICALLY CONTROLLED EXCISION OF CANCER

FREDERIC E MOHS, MD
MADISON, WIS

WITH THE TECHNICAL ASSISTANCE OF JEAN TURNBULL RYAN

THE microscopic control of excision which characterizes the chemosurgical technique for the treatment of cancer is attained by the use of frozen sections of specimens removed from the areas under suspicion. As previously described,^{1,6} the chemosurgical technique consists of the following steps: (1) the fixation in situ of the tissues by the application of a paste containing a fixative chemical such as zinc chloride; (2) the excision of a layer of fixed tissue which is divided into convenient specimens, the locations of which are mapped on paper and on the lesion; (3) the preparation of frozen sections by cutting through the under surface of each specimen; (4) the scanning of the sections under the microscope so that the remaining areas of cancer can be indicated on the map; (5) reapplication of the fixative to the cancerous parts of the lesion; (6) repetition of the process until the entire area is free of cancer.

This article concerns the microtechnical procedures by which the frozen sections are made. Special consideration of the frozen section technique as applied to the chemosurgical specimen is desirable because of the importance of obtaining complete sections of the specimens which often are rather large and sometimes are friable. The sections must be complete because if any part of a specimen is lost during the sectioning process, the operator cannot know whether the lost tissue was cancerous or noncancerous and therefore cannot know whether further treatment is required. These considerations have necessitated the development of some new details of technique. The usual procedures for the preparation of frozen sections along with the modifications which have been found useful are given herewith.

TECHNIQUE

Mounting of the Specimens—The specimens as they are excised from the lesion are usually flat pieces of tissue which are approximately 1 cm across. Since it is the under surface of these specimens that is to be investigated, the specimen is frozen on the stage by placing it in a small pool of albumin solution* which has been partially frozen by rapidly opening and closing the valve

This work was supported by the Thomas E. Brittingham Fund, the Jonathan Bowman Memorial Fund, and the Wisconsin Alumni Research Foundation.

From the Chemosurgery Clinic, Wisconsin General Hospital and McArdle Memorial Laboratory, University of Wisconsin Medical School.

Received for publication, Dec. 5, 1947.

*Albumin solution is used because when it freezes the ice is not so hard and brittle as when plain water is used. It also holds the specimen on the stage more firmly. It is made by adding approximately 0.5 Gm of albumin to 30 cc of water and preserving with a drop of 95 per cent phenol.

several times. Although the specimen has ordinarily been flattened before placement upon the stage, it is often necessary to elevate one or more edges by cutting into the ice under the specimen with a knife. If the tissue is irregular in thickness it may be necessary to flatten it with the broad surface of a scalpel handle before mounting it on the stage.

It is important that the specimen be oriented so that the microtome knife strikes the narrowest part of the specimen first and moves diagonally over the greatest area (Fig 1, A, B, C, and D). Specimens containing connective tissue, muscle fibers, or cartilage should be mounted so that the fibers (or the long axis of the cartilage) are parallel to the direction of movement of the knife.

Fig 1—Diagrams showing the recommended angle at which the microtome knife should meet specimens of different shapes and consistencies

(Fig 1, E and F) If a vertical section of the flat piece of tissue is cut its long axis is placed at an angle of about 65° in relation to the knife (Fig 1 G). The specimen should never be placed so that the entire edge meets the knife at the same time because this will crush the tissue, cause the knife to jump over the specimen, or push the entire block off the stage.

Specimens containing skin are placed so that the skin edge is not cut first. Likewise tissues which are heterogeneous in consistency are placed so that the softer part of the tissue is cut first. This provides a firm backing for the knife to cut against.

Cutting of the Specimen—When the block of ice has been frozen to the optimum degree of hardness, the section is cut with the microtome knife which is usually used dry and at room temperature. Each section that is cut adheres to the blade and is removed with the moist finger and placed in a glass dish of cold water. If the tissues are fragile this operation must be done gently. If the tissues are pulled apart by the surface tension as they are placed in the water, it is advisable to add a few drops of an aqueous solution of a surface tension depressant such as Zepluran.

Sections are best cut at a thickness of 15 to 25 microns. If the tissues are cut thinner, those that do not contain fairly large amounts of connective

tissue will fall apart. Cancer tissues with a meager connective tissue stroma, fatty tissues, and tissues heavily infiltrated with leucocytes are likely to be fragile, while tissue containing cartilage and considerable amounts of connective tissue will hold together even though cut very thin.

It is particularly important that the knife be kept very sharp. Ordinarily it should be stropped daily and honed weekly. For best results the microtome should be one which is constructed so that the knife is held firmly. A knife-holder which slides on tracks, such as in the Bausch and Lomb clinical microtome is satisfactory from this standpoint.

Ordinarily, four or five complete sections are cut from each specimen. The water in the dish is changed after cutting each specimen so as to avoid mixing of the sections from different specimens.

Mounting of the Sections—The sections are worked onto the slide with a curved metal teasing needle. If there is a tendency for the specimen to break up it is important that the fragments be pieced together so that no part of the section is missing. The edges of the specimens usually have been marked with coloring materials (methylom, washing bluing, and India ink) for the purpose of orientation when the sections are examined under the microscope. These markings which persist throughout the staining process and in the rearrangement of any fragments which may fall out. Any folded areas may be remounted by floating off that area and remounting without detaching the whole section. If the section is curled up it may be uncurled by attaching one edge to the slide and drawing the slide out of the water so as to unroll it. If the section is not too fragile, it frequently is possible to work the roll loose by gently moving it around in the water with the wire teaser.

It usually is advisable to put three sections on one slide, particularly if they are fragile and if there is some likelihood of the sections being incomplete. However, one good section is all that is necessary. The slide is then blotted carefully and thoroughly with a very dry soft towel, preferably an old one that has the lint washed from it. It is best to blot only one of the sections first to see if the section will cling to the towel. If it does so, the other sections may be fixed to the slide by passing it through an alcohol flame several times. The slide is numbered with a wax pencil and put in 95 per cent alcohol to await staining.

Staining—The various solutions used in the staining process are kept in Coplin jars. These jars contain five slots so it is convenient to run five slides at a time, keeping slide number one in slot number one, slide number two in slot number two, and so forth. Some of the slides may be run ahead as long as they are kept in their proper slot so that there is no danger of getting the sections mixed.

The procedure for the dehydration, staining, clearing, and mounting of the sections is as follows:

1 *Ninety-five per cent alcohol* The slide may be left in this solution for any time over fifteen seconds.

2 *Cellulose nitrate (Parlodion*) solution* The slide is quickly dipped

*Mallinckrodt Chemical Works, St. Louis, Mo.

in this solution which should be rather thin. If it is too thick it and the sections tend to peel off the slide. Moreover a thick layer prevents the ready penetration of the stain and prolongs the process. The solution is made by dissolving one stick (1 Gm.) of paralodion in 30 cc. of a solution of equal parts of ether and 95 per cent alcohol. After dipping in the cellulose nitrate solution the slide is dried by immediately blotting firmly with a clean dry towel.

3 *Hematoxylin* Approximately two minutes is the usual staining time but the slide may be left in longer if the tissue does not take the stain well. Delafield's hematoxylin is used. This stain lasts indefinitely but it is advisable to filter off the precipitate every day before using. After staining the excess dye is washed off the slide in a dish of water.

4 *Acid alcohol* This solution is just strong enough to destain the average section with one dip. It is made by adding 25 cc. of concentrated hydrochloric acid to 500 cc. of 70 per cent ethanol. This solution is changed once a week or more often if necessary.

5 *Alkaline water* If the tap water is alkaline it is convenient to let the slide stand in a dish of water to alkalize. Otherwise a weak solution of sodium bicarbonate is used and the sections are allowed to remain in the solution until they are blue. This usually takes one or two minutes. Only one slide should be in the solution at a time because the sections may loosen and come off at this time and be mixed. If a section floats off it may be mounted as before, blotted with a dry towel, and continued in the staining process. It is advisable to blot the sections at this stage to insure the removal of water and bubbles from under the sections.

6 *Eosin* The solution is adjusted so that one dip of the section gives adequate staining. The stock solution is made as follows. Dissolve 2.5 Gm. aqueous eosin in 500 cc. distilled water. Add 4 cc. of concentrated hydrochloric acid and 1 cc. of glacial acetic acid. Pour off the supernatant and save the precipitate which is washed six times with water. Filter and dry the precipitate. There will be about 0.5 Gm. of precipitate. This is dissolved in 100 cc. of 95 per cent alcohol. The stain may be diluted with 95 per cent alcohol if it stains too deeply. Alcohol is also added as needed to replace that lost by evaporation. The solution should be filtered whenever particulate matter gathers in it.

7 *Alcohol and ether* Treat with this solution for two minutes or more. This solution is made up of equal parts of ether and 95 per cent alcohol and it should be changed daily.

8 *Absolute alcohol* Treat with this solution for one to two minutes or until all of the paralodion is removed. This solution should be changed once a week or more often if necessary for complete dehydration of the sections.

9 *Carbol xylol* Treat with this solution until the tissues are clear. Two minutes or more may be required. The stock solution is made by adding 300 cc. of xylol to 100 Gm. of phenol crystals. The solution ordinarily is changed once a week.

10 *Xylol* Treat with this for two minutes or more Change the solution weekly

11 *Mount in Clarite* and cover with a 22 by 50 mm cover slip This large size cover slip is desirable because several sections are placed on each slide The clarite solution is made by dissolving 60 Gm of clarite "X" hydrocarbon resin in 40 cc of toluene Clarite is preferable to balsam because it hardens more rapidly and because it does not become yellow with age

Sections made with this technique have not deteriorated after periods of over twelve years

SUMMARY

The microscopic control of excision attained by the chemosurgical treatment of cancer is dependent upon the completeness of the frozen sections of the tissues which have been fixed in situ prior to excision To make possible these complete sections a number of modifications of the usual frozen section technique have been devised A procedure embodying these modifications is described The sections, which are stained with hematoxylin and eosin, are permanent

Erratum

In the paper by Dominguez, Coreoran, and Page, *Mannitol Kinetics of Distribution, Excretion, and Utilization in Human Beings*, which appeared in the October issue of the *JOURNAL* (32 1192, 1947) equation 13 of Table I should be

$$V = \frac{A_2 (\beta^2 a + \alpha^2 b)}{\alpha \beta (\beta a + \alpha b)}$$

or, in terms of G,

$$V_1 = \frac{G (\beta^2 a + \alpha^2 b)}{(\beta a + \alpha b)^2}$$

PTEROYLGLUTAMIC ACID DEFICIENCY IN SWINE EFFECTS OF TREATMENT WITH PTEROYLGLUTAMIC ACID LIVER EXTRACT AND PROTEIN

GEORGE E. CARTWRIGHT, MD JANE FAX,* MD BETTY TATTING BS AND
MAXWELL M. WINTPOBE, MD PH D
SALT LAKE CITY, UTAH

THE discovery of the effectiveness of pteroylglutamic acid in the treatment of the macrocytic anemias has, so far, failed to clarify our understanding of the pathogenesis of these anemias¹. It has now been demonstrated that neither pteroylglutamic acid nor its naturally occurring conjugate the heptaglutamate, is the extrinsic factor the intrinsic factor or the potent antipernicious anemia substance in purified liver extract. Furthermore it has become increasingly evident that pteroylglutamic acid neither corrects nor prevents the neurological manifestations of pernicious anemia². With regard to the role of pteroylglutamic acid in pernicious anemia it has been suggested that in some patients with this disorder there is in addition to other metabolic defects an inability to utilize the naturally occurring pteroylheptaglutamate³. It has also been proposed that pteroylglutamic acid and the antipernicious anemia principle of liver may function via unrelated pathways⁴.

The purpose of this paper is to describe the hematologic manifestations of pteroylglutamic acid deficiency in swine produced by the administration of a synthetic substance having an action antagonistic to that of pteroylglutamic acid and to compare the therapeutic effectiveness of purified liver extract and synthetic pteroylglutamic acid in this condition. This report leaves many questions unanswered and therefore must be considered preliminary in nature. The observations are now being amplified and extended.

The pteroylglutamic acid antagonist used in these experiments (N67†) was prepared‡ by allowing 2, 4, 5 triamino 6 hydroxypyrimidine and p amino benzoyl 1(+) glutamic acid to react with 2, 3 dibromobutyraldehyde. Since the reaction product (N67) has not been purified it has been termed crude methyl folie acid. The product of the reaction described has been designated by Martin, Tolman and Moss⁵ as 7 methylfolie acid. The substance antagonizes reversibly the effect of pteroylglutamic acid on the growth of *Streptococcus faecalis* R and of *Lactobacillus casei*⁶. Different inhibiting ratios have been reported for the two organisms. The ratio of antagonist to pteroylglutamic acid for *Str faecalis* R is 20:1 and for *L casei* about 1:1000:1.

11 *Mount in Clarite* and cover with a 22 by 50 mm cover slip This large size cover slip is desirable because several sections are placed on each slide The clarite solution is made by dissolving 60 Gm of clarite "X" hydrocarbon resin in 40 cc of toluene Clarite is preferable to balsam because it hardens more rapidly and because it does not become yellow with age

Sections made with this technique have not deteriorated after periods of over twelve years

(milligrams per kilogram body weight daily) thiamin hydrochloride 0.25 riboflavin, 0.12, nicotinic acid 1.20, pyridoxine hydrochloride 0.20 calcium pantothenate 0.50, choline chloride 50.00 para-aminobenzoic acid 0.10 inositol 0.10 pteroylglutamic acid 0.30. In addition all animals received crystalline biotin 50 μ per kilogram body weight per week intramuscularly. Sulfasuxidine when given was added to the basal diet in amounts of 2.0 per cent. The antagonist when given was administered daily in capsules in amounts of 0.2 per cent of the basal diet (equivalent to 0.06 gm per kilogram body weight). Full details of the experimental methods have been published elsewhere.¹

The four animals receiving the antagonist were first depleted of pteroylglutamic acid for periods of eighty six to one hundred twenty two days by a diet lacking pteroylglutamic acid supplemented with sulfasuxidine.

Plasma iron determinations were made by the method of Bailan and Walker.¹¹ Serum copper was measured by the method of Critchfield, Jones and Wintrobe.¹ For the determination of free erythrocyte protoporphyrin the method of Grimstead and Watson¹² was used.

Specimens of bone marrow were obtained by aspiration of the sternal marrow with standard 16 gauge sternal puncture needles. A small amount of marrow fluid usually less than 0.3 ml. was withdrawn into a clean dry syringe and thin cover glass preparations were drawn and stained with Wright's stain. From 500 to 1500 cells were counted in each preparation. The figures are expressed in per cent of total cells counted.

In order to determine whether or not extrinsic factor is present in the crude casen used in these studies the material was assayed in three patients with classic uncomplicated idiosyncratic pernicious anemia. The procedure of assay was as follows. The patients were hospitalized and during the assay periods liver meat meat products milk and poultry were excluded from the diet. Bread cereals sugar fats vegetables and fruits were permitted in the amounts desired. Fifty gram of the casen to be assayed were incubated at 37° C. for two hours with 150 to 200 ml. of normal human gastric juice at pH 2.5 to 3.5. The incubation mixture was then strained through cheesecloth, the filtrate was neutralized to pH 5 and administered immediately to the patient. The results

of the assays are presented in Table I. Patient J S was given, in addition to the filtrate, an alcoholic extract from crude casein. This was prepared by adding 18 liters of 65 per cent ethanol to 6 kg of casein. The casein-alcohol mixture was allowed to stand for forty-eight hours at room temperature with intermittent shaking. The alcohol was then filtered off and distilled in vacuo to dryness. The residue was extracted with several volumes of ethyl ether to remove the fats, and dried at room temperature, and then pulverized. One tenth of the resulting residue was added daily to the crude casein prior to incubation.

As seen in Table I following the administration of the described mixture to Patient J S a reticulocytosis of 84 per cent developed and in twenty days the volume of packed red cells increased from 24.2 ml per 100 ml to 34.0. One unit of purified liver extract (15 units per milliliter) was then administered intramuscularly daily for ten days. No secondary reticulocyte response occurred. Patient N B was given crude casein, extracted three times as described plus the residue from the third alcohol extraction. As can be seen, the extraction procedure failed to remove the extrinsic factor activity and a reticulocytosis developed which reached a maximum of 12.8 per cent. One unit of liver extract daily again failed to elicit a secondary reticulocytosis. Patient S S was given 50 Gm of the crude casein daily without the addition of an alcoholic extract. A reticulocytosis of 9.0 per cent developed and the volume of packed red cells rose from 27.0 ml per 100 ml to 31.8 in sixteen days. Following this, the daily intramuscular injection of 1 unit of purified liver extract failed to produce a secondary reticulocytosis.

Since the administration of a total of 500 Gm of crude casein caused a significant response in Patient S S and since the animals received approximately 15 to 120 Gm of crude casein daily for about 190 days, it must be concluded that our experimental animals were receiving substantial amounts of extrinsic factor. It is unlikely that the response in the patients with pernicious anemia was due to the pteroylglutamic acid content of the crude casein since the total pteroylglutamic acid content of the casein, after enzymatic digestion as determined titrimetrically with *L* casein by the method of Teph and Elvehjem¹⁴ was found to be only 0.009 μ g per 100 Gm of casein. The alcohol extracted casein was found to contain only 0.006 μ g per cent by this method.*

RESULTS

General—The animals receiving the pteroylglutamic acid antagonist became listless and weak and ate poorly. Hair loss was not extensive but the hair became thin and lusterless. The general appearance of the animals was extremely untidy. The abdominal walls of the pigs sagged, probably due to loss of muscle tone. As the deficiency progressed, then squeals became faint and weak.

A moderately severe diarrhea was present, the stools being somewhat orange-yellow in color due presumably to the presence of antagonist. Growth was poor, and about equal, in both the control and antagonist groups due to the low content of protein (10 per cent) in the diet. Oral lesions were not observed.

*We are indebted to Dr J M Cooperman, Hoffmann-La Roche Inc., Nutley, N. J. for these determinations.

Peripheral Blood—In contrast to the control animals those receiving the antagonist became markedly anemic in twenty one to forty two days. The volume of packed red cells decreased from a level of about 35 ml to approximately 20 ml per 100 ml (Table II Figs 1-4). The anemia at this time was normocytic. Examination of the blood smears revealed marked anisocytosis without a significant degree of poikilocytosis, an increase in Howell Jolly bodies, frequent nucleated red blood cells, and moderate polychromatophilia. Unusually large macrocytes were frequently seen but microcytes were equally numerous. This is illustrated in Fig. 6.

As shown in Table III the animals receiving the antagonist developed a mild leucopenia and severe neutropenia. The mean total leucocyte count for the control group was 15 000 per cubic millimeter, as compared with 10 500 for the pigs receiving the antagonist. The percentage of granulocytes (metamyelocytes, neutrophils, basophils and eosinophils) was reduced in the antagonist group to 14 as compared with a mean of 47 for the control group. The absolute number of granulocytes in the control animals averaged 7 000 per cubic millimeter of blood, whereas in the animals receiving the antagonist there were only 1 500 per cubic millimeter. Giant metamyelocytes and multinucleated neutrophils such as are found in the blood smears of patients with pernicious anemia were not seen in the blood of the pigs.

The number of platelets per cubic millimeter of blood in the control animals ranged from 310,000 to 510 000. The number of platelets per cubic millimeter of blood in the animals receiving antagonist was extremely variable. Values between 100,000 and 310,000 were frequently obtained but in one animal (10 64) the number of platelets increased prior to therapy.

Bone Marrow—In Table IV the results of differential cell counts on sternal marrow obtained from the eight control animals and the four animals receiving antagonist are summarized. In the marrows from the animals receiving antagonist there was a marked reduction in the number of polymorphonuclear neutrophils and neutrophilic metamyelocytes as well as a slight increase in earlier forms of the myeloid series and a significant decrease in the leucocyte erythroid ratio. In addition extremely immature and somewhat abnormal nucleated red cells were present (Fig. 7). These cells were round or oval and extremely large measuring 12 to 25 μ in diameter, whereas the most immature nucleated

red cells seen in the marrow of the control animals measured 6 to 12 microns. These large cells possessed a relatively large nucleus and a somewhat homogeneous basophilic cytoplasm. The nuclei were composed of rather thin mesh like strands of chromatin. In some cells the chromatin showed some tendency to clump, in others the chromatin appeared finely granular and more homogeneous. The more immature of these cells contained two or three distinct nucleoli. A delicate nuclear membrane surrounded the nucleus. Later stages of this cell were present including the orthochromatic stage.

These cells resembled closely the megakaryoblastic series of cells seen in the marrow of patients with pernicious anemia, the only distinct difference being that the nuclear chromatin was not so fine and meshlike as that seen in human bone marrow. Whether or not the cells described in the pig megakaryoblasts is a matter for conjecture. In any event similar cells were not seen in the marrow of the control animals nor have they been observed by us in the marrow of animals following severe and prolonged hemorrhage superimposed on a dietary restriction of iron. For purposes of discussion these cells will be referred to as megakaryoblasts in this paper in order to distinguish them from cells of the normoblast series. On several occasions orthochromatic megakaryoblasts were seen in the peripheral blood of the deficient animals.

Plasma Iron Serum Copper and Erythrocyte Protoporphyrin—Plasma iron serum copper and erythrocyte protoporphyrin determinations are presented in Table V. These were made at the time of maximal anemia and prior to the initiation of therapy. No significant difference was noted in either the plasma iron or the erythrocyte protoporphyrin values in the two groups nor were these determinations appreciably different from those obtained in swine maintained on a diet containing 26 per cent casein. Animals maintained on a low protein diet have been found to have a significantly low serum copper.*

The serum copper in two of the animals receiving antagonist (10 53 and 10 64) was low, whereas in the other two (10 54 and 10 56) the values were comparable with those obtained in animals on a 26 per cent casein diet.¹⁰ The significance of this finding is not obvious

Fig 1—Anemia, leucopenia and neutropenia in a pig (10 53) receiving a pteroyl glutamic acid antagonist (N67). There was no hemopoietic response to the administration of casein or purified liver extract (LE) but a good response occurred when pteroylglutamic acid (PGA) was given.

MCV Mean corpuscular volume in cubic microns HT volume of packed red cells in ml/100 ml RETIC reticulocytes expressed in per cent WBC total leucocyte count in thousands per cmm PMN number of polymorphonuclear cells (mature neutrophils, basophils and eosinophils and metamyelocytes) in thousands per cmm of blood PLATELETS expressed in hundred thousands per cmm of blood IM intramuscular injection The purified liver extract used contained 15 USP units per milliliter

Effect of Therapy on the Peripheral Blood—One animal (10 53, Fig 1) was treated twelve days after the administration of antagonist was started by increasing the casein in the diet to 26 per cent. There was a temporary increase

in the volume of packed red cells but this increase was not sustained and the animal became severely anemic. There was no apparent increase in the total leucocyte or neutrophil counts and there was no significant reticulocytosis. The platelets increased from a low normal value of 300 000 per cubic millimeter to a value considerably above the normal (1 400 000) and then decreased to the thrombocytopenic level of 100 000. The protein therapy had no apparent effect on the mean corpuscular volume. There was however a significant growth response (Fig 5) and a rise in serum albumin from 2.1 Gm per cent to 3.2 Gm per cent.

Fig. —Development of anemia, leucopenia and neutropenia in a pig (1054) receiving a pteroylglutamic acid antagonist (N67) and response to purified liver extract (L.E.) and pteroylglutamic acid (PGA). For explanation see Fig. 1.

Three animals (1053, 1054, 1056, pigs 13) were treated with purified liver extract prior to pteroylglutamic acid therapy. In one (1053, Fig. 1) there was no significant effect on any of the blood constituents following the injection of 150 units. In the other two (1054, 1056, Figs. 2 and 3) there was a suboptimal response consisting of a reticulocytosis of 15 per cent in one animal (1054, Fig. 2) and a modest rise in volume of packed red cells and platelets in both. In one pig (1054, Fig. 2) the total leucocyte count had risen to normal at the time liver therapy was begun. There was no apparent effect from the liver therapy and neutropenia developed again. In the other animal (1056, Fig. 3) the total leucocyte and neutrophil values rose to normal but were not sustained.

These three animals (10-53, 10-54, 10-56, Figs 1-3) were then treated with synthetic pteroylglutamic acid and an immediate, rapid, and maximal increase in the volume of packed red cells followed. In two of the pigs (10-53, 10-54, Figs 1 and 2) a significant reticulocytosis of 16 and 15 per cent, respectively, appeared. An initial rise in the platelet count was observed in two of the animals (10-53, 10-54, Figs 1 and 2), but in the three (10-54, 10-56, 10-64, Figs 2-4) in which the platelets were followed for a significant period of time

Fig. 3.—Anemia, leucopenia, and neutropenia in a pig (10-56) receiving a pteroylglutamic acid antagonist (N67). There was a questionable response to purified liver extract (L.E.) and a well-marked response to pteroylglutamic acid (PGA). For symbols see Fig. 1.

thrombocytopenia reappeared. In two of the pigs (10-54, 10-56, Figs 2 and 3) the leucopenia and neutropenia disappeared following pteroylglutamic acid therapy. In the third (10-53, Fig. 1), this effect was not observed and only a slight, transient increase in the total leucocyte count was noted.

All three of the pigs treated initially with liver (Figs 1-3) developed definite but not marked macrocytosis following liver therapy (Fig. 6). The mean value for the mean corpuscular volume in the control group (twenty-four determinations in five animals) was 56 ± 5.16 cubic microns with a range of 45 to 69 cubic microns. Only twice were the values above 59 cubic microns. In all three of the pigs treated with liver the mean corpuscular volumes reached 72 cubic microns. The macrocytosis could not be attributed to the presence of reticulocytes since these were not significantly increased. In the pigs (Figs 2 and 3) in which the mean corpuscular volume was followed for a significant

Fig 4—Anemia leucopenia and neutropenia in a pig (10 64) receiving a pteroyl glutamic acid antagonist (N67). There was a pronounced response to pteroyl glutamic acid (PGA) but purified liver extract (LE) had no effect. For explanation see Fig 1.

Fig 5—Growth curves of the four animals receiving the pteroyl glutamic acid antagonist (N67).

period after pteroylglutamic acid therapy the macrocytosis disappeared (Fig 6). Likewise the anisocytosis and polychromatophilia disappeared, and the Howell-Jolly bodies and nucleated red cells diminished in numbers. This was not the case following liver therapy. As already noted, macrocytosis developed and, in addition, nucleated red cells, Howell-Jolly bodies, and polychromatophilic cells persisted in increased numbers.

Fig 6—Photomicrographs of peripheral blood smears ($\times 1000$). A-1 Normal pig (10.50) mean corpuscular volume (MCV) 57 cubic microns. A-2 Pig (10.56) receiving PGA antagonist (129th day of experiment) the smear was made after liver extract had been given and prior to PGA therapy, note marked anisocytosis and numerous macrocytes. MCV 63 cubic microns. A-3 From same animal as in A-2 after PGA therapy (183rd day), note decrease in anisocytosis and absence of macrocytes. MCV 57 cubic microns. B-1 Pig (10.51) prior to administration of antagonist (120th day) MCV 64 cubic microns. B-2 From same pig as in B-1 but after the administration of antagonist (164th day) note marked anisocytosis and numerous macrocytes. MCV 69 cubic microns. B-3 From same pig as in B-2 after liver therapy (187th day) note macrocytosis. MCV 72 cubic microns.

Fig 4—Anemia leucopenia and neutropenia in a pig (10-64) receiving a pteroyl glutamic acid antagonist (N67). There was a pronounced response to pteroylglutamic acid (PGA) but purified liver extract (LE) had no effect. For explanation see Fig 1.

Fig 5—Growth curves of the four animals receiving the pteroylglutamic acid antagonist (N67).

period after pteroylglutamic acid therapy the macrocytosis disappeared (Fig 6). Likewise the anisocytosis and polychromatophilia disappeared, and the Howell-Jolly bodies and nucleated red cells diminished in numbers. This was not the case following liver therapy. As already noted, macrocytosis developed and, in addition, nucleated red cells, Howell-Jolly bodies, and polychromatophilic cells persisted in increased numbers.

(15 units per cubic centimeter) in units PCA picrovitalstainic acid in milligrams

rise in the volume of packed red cells to the level observed in pigs on the low protein diet and an increase in the leucocyte and neutrophil count occurred. There was no apparent increase in platelets. A secondary reticulocytosis was not elicited by the administration of 150 units of liver extract and no further increase in the volume of packed red cells was noted. A significant macrocytosis was not present in this animal at any time.

The effects of the various therapeutic agents on growth are shown in Fig. 5.

Effect of Therapy on the Bone Marrow—The effects of therapy on the bone marrow of each of the animals receiving the antagonist are presented in detail in Table VI.

The administration of liver extract was associated with a diminution in the number of megaloblasts in the marrow in each instance (Figs. 10 53, 10 54 and 10 56) but did not result in a complete disappearance of these cells. Cells were seen following liver therapy which had characteristics intermediate between basophilic normoblasts and megaloblasts. In two of the animals (10 53 and 10 54) the leucocyte erythroid ratio became more abnormal following liver therapy, whereas in the third (10 56) the ratio reverted to normal. In one pig (10 53) liver therapy had no apparent effect on the maturation of the leucocytes; in another (10 54) there was a significant increase in metamyelocytes followed later by an increase in neutrophils, whereas in the third there was a marked increase in metamyelocytes and a significant increase in neutrophils. In general the changes in the bone marrow following liver therapy were consistent with those seen in the peripheral blood.

Pteroylglutamic acid therapy resulted in a restoration of the bone marrow to normal in three instances. In one pig (10 53) although the megaloblasts disappeared completely and the leucocyte erythroid ratio returned to normal there was an increase in the percentage of lymphocytes and a decrease in metamyelocytes and neutrophils. In this animal the leucopenia and neutropenia in the peripheral blood persisted in spite of therapy.

At the termination of the experiment the animals were sacrificed and autopsies performed. There was no splenic enlargement and the marrow in the sternum, ribs, vertebrae and femurs was red and hyperplastic. There were no significant microscopic abnormalities in any of the organs examined which could not be attributed to a deficiency of protein.

DISCUSSION

The observations presented here indicate that there is a marked difference between the effect of pteroylglutamic acid and that of liver extract of the pernicious anemia type in pigs fed low protein diets and receiving a folic acid antagonist. The administration of liver extract was associated with a good reticulocyte response and a modest rise in volume of packed red cells in one animal (10 54) but in another (10 56) the effect was less impressive, and in a third (10 53) no significant change was observed in the blood even though a very large amount of liver extract, 150 units was given. The administration of pteroylglutamic acid on the other hand, was associated with a well pronounced hemopoietic response in these three animals as well as in another (10 64) not previously treated with liver extract.

These results are not in accord with the observations of Henle, Welch, and co-workers⁷ who concluded that "extrinsic factor and purified liver extracts are effective even though folic acid is not available to the animal." There are, however, several differences in the experimental conditions employed by the Cleveland group and by ourselves. Our animals received a diet low in protein. Presumably the three pigs reported by Welch, Henle, and colleagues received adequate amounts of protein. Furthermore their animals were given Labco⁸ 'vitamin-free' casein which contains little or no extrinsic factor,¹⁸ while our animals were fed casein proved to contain substantial quantities of extrinsic factor. Finally, our animals were depleted of pteroylglutamic acid for a prolonged period prior to the administration of antagonist. Whether these differences in experimental procedure are significant or important cannot be stated at this time. It should be noted that the response of the one animal reported in detail by the Cleveland group was, for a pig, considerably delayed and gradual.⁶

From one point of view it may be considered surprising that any hemopoietic response to liver extract should have been observed in our animals. There is no reason to assume that there was in these animals a deficiency of intrinsic factor although this was not specifically investigated. They were fed what would seem to be, at least in terms of treating a patient with pernicious anemia, a rather substantial amount of extrinsic factor. One might ask whether under the conditions of the experiment, when a low protein diet, sulfasuxidine, and antagonist were administered, our animals actually absorbed an adequate amount of extrinsic factor. Since diarrhea was present absorption may not have been complete. The theoretic though remote possibility that extrinsic factor can be synthesized in the intestinal tract by bacteria must not be overlooked. If this were true, the administration of both sulfasuxidine and antagonist might seriously hinder such synthesis. In favor of the existence of a double deficiency that is both of extrinsic factor and of pteroylglutamic acid, is the fact that in the animal treated first with protein (10-53) there was no significant response to the subsequent administration of purified liver extract. However, contradicting this hypothesis is the fact that Pig 10-64 responded maximally to 20 mg of pteroylglutamic acid without prior feeding of increased amounts of casein. Furthermore, the administration of 150 units of liver extract sixteen days later failed to produce a secondary response. It may be mentioned here that in other experiments with pigs maintained on a low protein diet which were repeatedly depleted of niacin, we have observed no response to liver extract.¹⁹

A more plausible explanation of the activity of liver extract, such as it was, would be that a substance which it contains is concerned in some way with the utilization or availability of pteroylglutamic acid and that the administration of the large doses of liver extract made small tissue stores of pteroylglutamic acid available to the animal or that pteroylglutamic acid was released from more complex compounds. In patients with pernicious anemia in relapse Bethell and co-workers¹⁶ as well as Welch and associates^{1, 2} have observed that a substance in purified liver extract may contribute to the utilization of con-

¹⁸The Borden Co. New York N. Y.

jugates of folic acid. The possibility that liver extract makes small amounts of pteroylglutamic acid available from the tissues is now under investigation in the current animal experiment.

Since the doses of liver extract used were large (75 to 150 units) it is unlikely that their unimpressive effect was due to inadequate dosage. The response which seemed to occur probably cannot be explained on the basis of the pteroylglutamic acid content of the liver extract since it has been shown that this preparation contains less than $10 \mu\text{g}$ of microbiologically determinable *L. casei* factor per milliliter.⁸ Furthermore if the response was due to pteroylglutamic acid or its precursors in the liver extract Pig 10 56 should have responded when 10 ml of liver extract were administered. Instead there was a slight initial response to 1 ml of liver extract and no further response when 10 ml were given eighteen days later. Again the complete lack of response to 150 units in Pig 10 53 is noteworthy.

It is of interest that the anemia observed was normocytic at first. Smears of the peripheral blood during this period revealed numerous large macrocytes and a comparable number of microcytes. After liver therapy in three animals definite macrocytosis appeared and this persisted beyond the period of reticulocytosis. It seems unlikely that the macrocytosis was due to liver therapy although this possibility has not been ruled out. A more plausible explanation would seem to be that sufficient time had not elapsed for a significant degree of macrocytosis to develop which would be manifest when mean values were determined. Provided the life span of the red cell of the pig is similar to that of man, that is about 120 days, replacement of the circulating normal sized red corpuscles by macrocytes with a corresponding increase in the mean corpuscular volume could not be expected in twenty to forty days. Since the liver had little or no effect on the anemia, a further period of forty six to sixty one days was available after liver therapy during which macrocytosis might develop. Although it is true that the one animal not treated initially with liver failed to develop macrocytosis it must be noted that this animal received the antagonist for only thirty five days prior to the administration of pteroylglutamic acid. It is of interest that the one pig reported in detail by Weleh, Hemle and co workers⁹ did not develop significant macrocytosis until the post treatment period.

The response of the leucocytes to liver extract and pteroylglutamic acid therapy is difficult to interpret. In several instances the values appeared to be rising at the time therapy was begun. In one animal there was no response to either substance. Although the anemia of the pig reported by Weleh and associates⁹ responded to the therapy given the leucocyte and neutrophil counts did not return to normal. It seems possible that a substance other than pteroylglutamic acid or the antipermeous anemia factor is involved. The platelet values in our animals are also exceedingly difficult to interpret. They appeared to be a transient thrombocytosis in association with protein, liver or pteroylglutamic acid therapy followed by a decrease to an abnormally low level. More information is needed before definite conclusions can be drawn concerning the leucocytes and platelets.

There are various possible explanations of the relationship of liver extract factor and pteroylglutamic acid in hemopoiesis. It has been pointed out already, for example, that the liver factor may be concerned with the liberation of pteroylglutamic acid from conjugated forms of this substance in the tissue stores. If this were true, one would expect both liver extract and pteroylglutamic acid the substance it makes available, to be effective in producing a hemopoietic response in pernicious anemia. One would also expect that pteroylglutamic acid deficiency, if this included a deficiency of conjugates as well as of free forms of the vitamin, would not be affected by the administration of liver extract. If a deficiency of extrinsic factor were produced, one would expect a response to occur when extrinsic factor or liver extract or pteroylglutamic acid was given.

Such an hypothesis would be consistent with our own report²⁰ in which an anemic pig fed a highly purified diet responded to the administration of liver extract if we assume that that animal was deficient in extrinsic factor and was at most, only partially deficient in pteroylglutamic acid and its conjugates. It would explain the findings of Welch, Heinle, and co-workers⁶ if it can be assumed that their animals were deficient in extrinsic factor and only partially deficient in pteroylglutamic acid and its conjugates, and it would be satisfied by our own observations, presented in this report, if it is assumed that our animals were mainly deficient in pteroylglutamic acid and its conjugates. The unimpressive effect of liver extracts and the variations in the different animals could be explained by assuming that only a moderate or slight deficiency of extrinsic factor was produced in our animals when a crude casein containing extrinsic factor was fed in low amounts.

Totter Sims, and Day,²¹ on the basis of indirect evidence, have suggested that pteroylglutamic acid is concerned with the synthesis of protoporphyrin. The data on free erythrocyte protoporphyrin presented here do not substantiate this but admittedly do not disprove the theory.

It may be mentioned, in closing, that a pronounced ataxia appeared in one animal (10-64) approximately ten days after the administration of 20 mg of pteroylglutamic acid. A similar phenomenon has been observed in animals fed a diet deficient only in protein. This will be the subject of a separate report.

SUMMARY

Four pigs were maintained on a synthetic diet containing 10 per cent crude casein which was shown to possess extrinsic factor activity. The diet was supplemented with various vitamins, exclusive of pteroylglutamic acid, p-aminobenzoic acid, and inositol, sulfasuxidine and a pteroylglutamic acid antagonist were given as well. A severe anemia, leucopenia, and neutropenia developed. No such changes were observed in the blood of eight control animals maintained on the same diet plus pteroylglutamic acid, p-aminobenzoic acid, and inositol and to which no sulfasuxidine or pteroylglutamic acid antagonist was added.

Studies on the bone marrow of the animals receiving the pteroylglutamic acid antagonist revealed a marked reduction in the number of polymorphonuclear neutrophils and neutrophilic metamyelocytes, with a slight increase in the earlier forms of the myeloid series and a significant decrease in the leucocyte erythroid

ratio. In addition, immature and nucleated red cells in many ways similar to those seen in the bone marrow of patients with pernicious anemia in relapse were observed.

The anemia became more pronounced in spite of a great increase in the protein content of the diet of one animal. It responded partially to the administration of liver extract in one animal, questionably in another, and not at all in a third. Rapid relief of the anemia followed the administration of small doses of pteroylglutamic acid in all four pigs.

Macrocytosis developed as the anemia progressed but at first the mean corpuscular volume was normal, probably because of the presence of many microcytes. In the later stages of the disorder macrocytic anemia was demonstrated, many more macrocytes than microcytes being present.

The leucopenia and neutropenia were not permanently relieved by either protein or liver therapy. In three of the animals the leucopenia and neutropenia were no longer present following the administration of pteroylglutamic acid. In one animal the leucopenia and neutropenia persisted even after protein, liver, and pteroylglutamic acid were given. The platelets increased markedly after the administration of protein, liver, or pteroylglutamic acid, but the increased levels were not sustained.

The data suggest that the antipernicious anemia substance in purified liver extract does not completely, if at all, replace pteroylglutamic acid in the nutrition of the pig.

The crude methylfolate acid antagonist (N67A, Lederle) and the pteroylglutamic acid were kindly furnished by the Lederle Laboratories, Pearl River, N. Y., through the courtesy of Mr. T. H. Jukes and Dr. S. M. Hardy.

Sulfasuxidine was generously furnished by Sharp & Dohme, Inc., Philadelphia, Pa., through the courtesy of Dr. W. A. Feiler.

Natolo was supplied by Parke Davis & Company, Detroit, Mich., through the courtesy of Dr. E. A. Sharp.

Biotin was obtained from Hoffmann-La Roche, Inc., Nutley, N. J., through the courtesy of Dr. E. L. Sevinghaus.

The vitamins, with the exception of pteroylglutamic acid and biotin, were kindly furnished by Merck and Company, Inc., Rahway, N. J., through the courtesy of the late Dr. D. F. Roberts.

We are indebted to Miss Helen Ashenbrucker, Miss Pauline Black, Mrs. Darlene Kehl, Miss Mary Hles, Mr. George Trappett, and Mr. Ocie Hadley for technical assistance.

A STUDY OF THE RESPONSE OF BACTERIAL POPULATIONS TO THE ACTION OF PENICILLIN A QUANTITATIVE DETERMINATION OF ITS EFFECT ON THE ORGANISMS

SOPHIE SPICER M.D. DR.P.H. AND DIANA BLITZ B.A.
NEW YORK N.Y.

THE action of penicillin on susceptible bacteria is still unknown despite the intense effort that is being made to discover the mechanism of its antibacterial action. While we fully realize the importance of a knowledge of the *modus operandi* of this valuable therapeutic agent we believe it equally important especially from the clinical standpoint to know what actually happens to the bacteria when exposed to the action of the drug. The first observation by Fleming¹ which led to the discovery of penicillin was that of lysis of staphylococci or destruction of organisms and yet the action of the antibiotic has been referred to since as bacteriostatic rather than bactericidal. The sensitivity tests on bacteria as performed today are evidently directed toward the determination of the inhibitory activity of the penicillin on the microorganisms. Even in assaying the antibiotics it is the inhibitory activity of the material on the standard test organism which is being considered. Results of penicillin sensitivity tests are reported in such terms as the minimum inhibiting concentration the titer of inhibition the minimum effective concentration and so forth. Some workers using a standard organism in their sensitivity tests compare the titer of the test with that of the standard and report their results as half as sensitive as the standard one quarter as sensitive and so on. Such reports only vaguely suggest the action of the drug on the bacteria. Although several accounts of the bactericidal effect of penicillin have recently been reported² the action is still referred to as bacteriostatic or interchangeably referred to as bacteriostatic and bactericidal.

It is the purpose of this communication to present experiments which show that it is possible to determine the exact condition of a bacterial population when exposed to the action of penicillin—the degree of sterilization the number killed and the number surviving the character of the survivors—and to discuss how these findings may influence and even lead to a modification of present day treatment of infectious diseases with the antibiotics.

MATERIAL AND METHOD

The organisms used in the experiments were pneumococci from cases of lobar pneumonia hemolytic streptococci from scarlet fever and erysipela. *Streptococcus viridans* strain from cases of subacute bacterial endocarditis and staphylococci from general septicemias. All except one strain (*Str. viridans*) were initial specimens that they were obtained from patients before penicillin treatment was instituted. The organisms were grown in phosphate buffered beef heart broth enriched when necessary with 3 per cent citrated horse plasma. Bacterial counts were made in nutrient agar poured plates, 3 per cent of citrated horse blood being added to the agar.

From the Research Laboratories of the Department of Health
Received for publication Dec. 10, 1947

Commercial sodium penicillin* and streptomycin hydrochloride† were employed in the sensitivity tests, and penicillinase‡ was used to inactivate the penicillin in the culture.

Of the several methods now in use for determining the sensitivity of bacteria to the antibiotic, the serial dilution method is considered to be the most reliable since it allows a wide range of penicillin concentrations. This method, briefly, is as follows. Twofold serial dilutions of penicillin using broth as diluent, are made in small tubes. The number of tubes set up in a test depends on the range of penicillin concentrations desired, usually twelve. The penicillin dilutions are contained in 0.5 ml of broth. To each tube 0.5 ml of a young culture, a five to six hour growth, diluted to 10^{-5} is added, giving a total of 1 ml in each tube. One tube containing culture without penicillin is added as control. The tubes are incubated at 37°C and are read the following day. The last clear tube in the series containing the least amount of penicillin which "inhibits" bacterial growth as judged by visual inspection is regarded as the indicator of the penicillin sensitivity of the organism tested. Two streaked plates are made from the last two clear tubes to "measure sterility."

Since visible lysis is a direct proof of destruction of bacteria, we decided first to subject each culture to such a test. For this purpose an opaque culture is needed to observe clearing. Diluting the culture, as is done in the described procedure, would not do, since the inoculated tubes look quite clear before incubation. Too many organisms (over night growth) on the other hand, would obscure lysis if it occurred only to a slight degree. A three to four hour culture, depending on the rate of growth of the particular organism, gave the desired turbidity and was used undiluted. The same culture was also tested when diluted to 10^{-4} to compare the sensitivity titers. The tenfold serial dilutions were used in agar poured plates for bacterial counts. The number of organisms in the inoculum in different tests generally varied from 100,000,000 to 300,000,000 in the straight culture and from 10,000 to 30,000 in the diluted culture although smaller numbers were occasionally employed. The turbidity of the cultures was read before incubation and one tube was placed in the refrigerator to compare directly with the incubated tubes the following morning as a check on the turbidity reading. The tubes were incubated at 37°C for eighteen hours. The turbidity of the cultures was read by comparing each tube with a standard consisting of a set of fuller's earth suspensions in tubes ranging from a slight turbidity (25) to a density through which a dark object barely could be seen (500), twenty tubes in all. The titer of sensitivity, when straight culture was used for inoculation, was considered the smallest amount of penicillin which gave a turbidity reading equal to that of the initial culture before incubation.

Knowing that minute amounts of penicillin may inhibit growth of sensitive bacteria, we suspected that the inoculum used to subculture in normal media for sterility tests carried with it sufficient penicillin to inhibit growth and thus cause faulty interpretation of results. In order to eliminate this possibility we diluted the cultures exposed to penicillin so that the final concentration of the drug in the poured plates was reduced to negligible amounts. Penicillinase, used to inactivate the penicillin in the cultures, gave results similar to those obtained by dilution, and, since it was more convenient, this method was employed routinely for bacterial counts in 1 unit per milliliter amounts.

RESULTS OF THE EXPERIMENTS

As can be seen from Table I, the destruction of organisms by lysis occurred in all the bacterial strains tested except four, those of *St. viridans* strains identified as *salivarius*. Two greenish streptococcus strains one an enterococcus and the other unidentified, were lysed but in higher concentrations of penicillin. The extent of bacteriolysis varied in the different species, pneumococci showing the most, staphylococci less, and hemolytic streptococci least.

Individual strains within the same species also differed but within a smaller margin. Lysis was not complete in any of the cultures, a residuum of viable cells always remaining even in the highest concentration of penicillin used that of 60 units per milliliter. In most instances the number of organisms surviving varied inversely with the degree of lysis.

Avery and Cullen⁸ have shown that pneumococcal autolysin, while having no action on living pneumococci, has a powerful lytic action on heat-killed pneumococci. Bionfenbrenner and Muckenfuss⁹ have shown the same to be true of staphylococci. It is, therefore, difficult to tell whether the lysis of these organisms was caused by the penicillin or whether the bacteria were first killed by the antibiotic and then autolyzed. It is possible that the lysis of pneumococci and staphylococci was a summation of effects of unfavorable influences on the bacterial cell. The lysis of hemolytic streptococci suggests that penicillin is capable of lysing bacteria by itself, since these organisms do not autolyze. Attempts to prepare autolysin from hemolytic streptococci have been unsuccessful.¹⁰

Table II represents a typical experiment performed with a *Str. viridans* strain. When the penicillin cultures were subcultured in normal media no growth appeared in the plates. Enough of the penicillin was evidently left in the tubes to still inhibit growth of the bacteria. However, when the penicillin in the tubes was inactivated with penicillinase and poured plates made, vast numbers of organisms were recovered, even from the tube containing 60 units per milliliter or 7,500 times as much as the titer of "inhibition" (0.008 unit per milliliter).

When undiluted straight cultures used in the initial inoculum yielded a large number of residual organisms, a proportional number of viable bacteria were recovered from the penicillin cultures in which diluted inoculum was employed. In more sensitive strains, on the other hand, in those yielding smaller numbers of residual organisms no viable cells were found on subculture when a diluted inoculum was used. These findings indicate that individual organisms in a bacterial strain may differ in their reaction to the effect of the antibiotic. When cells of a certain type are present in small numbers they will be eliminated by high dilutions. Therefore the cells capable of withstanding large amounts of penicillin, being present in insufficient numbers to be carried through the serial dilutions, were excluded when the culture was diluted ten thousand times (10^4). See Tables II and III.

Higher titers of inhibition were obtained with diluted rather than with undiluted cultures. This did not, however, indicate the true extent of susceptibility of the bacterial strain tested. A comparison of Tables II and III demonstrates this clearly. Here the sensitivity of a hemolytic streptococcus may be compared with that of a *Str. viridans* strain. Both are susceptible to the same extent according to the dilution method. However, when the penicillin in the tubes was inactivated with penicillinase and bacterial counts were made, much greater numbers of viable organisms were recovered in the *Str. viridans* strain than in the hemolytic streptococcus strain—23 per cent

* Serial diluted for counting.

survivals in the former is compared with a small fraction of 1 per cent in the latter. These facts may account for the general observation that bacteria tested by the present day methods show a greater sensitivity to penicillin *in vitro* than *in vivo*. The use of straight undiluted cultures in the tests gives results more approximating the sensitivity of bacteria *in vivo*.

The residual viable bacteria were found to be inhibited in low as well as in high concentrations of penicillin showing a wide range of inhibition. This was more evident in the tests in which the cultures used for inoculation were diluted. (See Table II.) It is probably due to the elimination of certain cells by the dilution, leaving a more uniform population.

Residual organisms (single colony culture) when retested that is on second exposure to penicillin showed no increase in resistance, or only a slight increase, and again yielded a residuum of viable cells similar to that of the original or parent strain. Lysis of cells, however, either did not occur, or occurred to a lesser degree than in the original culture. This again demonstrates the singular characteristic these residual cells have of being able to withstand the killing effect of the drug in high as well as in low concentration.

Since these findings point to the existence in a bacterial population of members differing in the manner in which they respond to the action of penicillin, it was thought advisable to test the residual bacteria which are capable of withstanding high concentrations of the drug with streptomycin in the hope that they might be susceptible to the latter antibiotic. For this purpose the following method was adopted.

Nutrient agar plates are seeded with an overnight growth of the culture to be tested by placing 0.3 ml. of the broth culture in the center of the plate and spreading it with a wire spreader so that an even, uniform film is produced. The plates are placed in the incubator for fifteen minutes with covers tilted for drying. Paper disks* are impregnated with high concentrations of the drugs. A sterile pointed forceps is used in handling the disks. Each disk is immersed in the solution the excess being drained off against the wall of the tube. The disks are carefully placed on the surface of the inoculated plate four to a plate: two disks with penicillin solution 100 units per milliliter, one disk with streptomycin 100 units per milliliter and one disk with plain broth for control.

The following morning the zones of inhibition are measured and the paper disks used for residual organisms as follows. With sterile forceps each disk is carefully picked up and each placed into 10 ml. of sterile broth. The tubes are well shaken to free the bacteria which adhere to the paper disks. The original concentration of penicillin is thus diluted tenfold and by plating 1 ml. of the washing it is further diluted so that the final concentration in the plate is about one hundredth that of the original concentration in the disk. Not considering the amount of the drug which was absorbed by the agar. If the disk does contain some remaining penicillin it is in negligible amount so that the possibility of its acting on the subculture may be excluded.

* Each disk 6 mm diameter, No. 2 disk to 10 units/ml, No. 10 disk to 100 units/ml.

Five milliliters of each washing are used for plating 1 ml to a plate. One penicillin disk washing is plated with plain agar for residual cell count and another with agar containing streptomycin 10 units per milliliter, for its effect on penicillin residual organisms. The plates are then incubated overnight. The following morning they are examined, a colony count is made and the number found in the five plates is multiplied by two to get the total number of residual organisms from each paper disk. In order to obtain a ratio of the normal organisms originally in contact with the disk and the remaining viable cells after incubation with the penicillin, one paper disk moistened with broth is placed on a seeded plate and kept in the refrigerator for about one hour to allow the broth in the disk to be absorbed by the agar. The paper disk is then washed in the manner described, the washing is serially diluted and plated for bacterial counts. These are compared with the number of colonies obtained from the penicillin disks. The proportion of killed and surviving bacteria is thus obtained.

It is the belief of some investigators that antibiotics in the same concentration work more effectively on small rather than large numbers of organisms. For this reason we tested small numbers of the test bacteria with the same concentration of streptomycin as was used with the residual cells.

The results of the experiments are summarized in Table IV. While the normal cultures in small as well as in large numbers showed resistance to high concentrations of streptomycin, the residual bacteria were susceptible to low concentrations of the drug in amounts easily maintained in the body of the patient.

One of the six strains of *Str. viridans* tested did not respond to this treatment. The residual organisms of this strain were not affected by the streptomycin in the concentration used for the other cultures. To show that this method is reliable, two pneumococcus strains which by the tube method yielded small numbers of residual cells, were also subjected to this test. In one there were no viable cells found on the paper disk. The other yielded twenty colonies while the zones of inhibition were similar to those which yielded large numbers of viable residual organisms.

DISCUSSION

The results of the foregoing experiments bring to light several important facts in regard to the response of penicillin-sensitive organisms to the action of the drug.

We have shown that penicillin exerts a definite bactericidal effect on all susceptible strains in amounts possible to maintain in the body of the patient. It is capable of actually destroying the great majority of organisms by lysis, or otherwise under normal cultural conditions. However, there are always some cells left which are capable of withstanding the killing effect of even large doses of penicillin, remaining viable but unable to multiply in its presence. This inhibitory action extends through a wide range of concentrations, so that large and small amounts of the drug have the same inhibitory effect on these residual organisms.

The tests also indicate a heterogeneity of bacterial cultures in regard to the ability of individual members to react to penicillin. There seem to exist in most bacterial cultures cells of at least three types, differing from each other in the manner in which they react to the drug, namely (1) Those which are destroyed by lysis, (2) those which are killed without lysis, (3) those which are capable of withstanding the killing action of penicillin, remaining viable but unable to multiply in the presence of the drug. That this threefold response of penicillin sensitive bacteria is not a chance occurrence may be seen from the following findings: (1) When a bacterial culture, on exposure to penicillin, yielded a large number of residual viable organisms it always gave a proportional number of inhibited cells in the cultures for which small inoculum (10^{-4}) was used. (2) In more sensitive strains, in those yielding small numbers of inhibited residual organisms, no viable cells were found in the cultures for which a small inoculum was used (10^{-4}), indicating that, being present in small numbers in the original culture, these cells were eliminated by the dilution. See Table V.

- Eliminated by dilution

It was previously shown by one of us (S. S.)¹¹ that individual organisms in a bacterial culture, or specimen, also possess different degrees of sensitivity, or resistance, to sulfonamides. However, what makes penicillin a much more potent antibacterial agent is the fact that while the sulfa drugs are only bacteriostatic, penicillin actually destroys the sensitive organisms, leaving, in most cases, only a small number of viable cells capable of withstanding the action of the drug.

We believe that the success of penicillin therapy depends directly on the number of residual organisms left viable after the initial treatment with penicillin. The very small numbers of residual viable organisms in strains of pneumococcus, hemolytic streptococcus, and some strains of staphylococcus, as shown by our tests, may account for the dramatic results so often obtained with penicillin when used in the treatment of acute infections caused by these organisms. On the other hand, the very large numbers of viable organisms found in *Str. viridans* strains, as our tests indicate, may account for the protracted treatment with penicillin necessary in cases of subacute bacterial endocarditis in which *Str. viridans* is the most frequent etiological agent.

With the belief that individual organisms in a given culture possess different inherent characteristics in regard to drug susceptibility, we thought that the residual cells capable of withstanding large amounts of penicillin might perchance be sensitive to the action of other therapeutic agents. We therefore treated bacteria, which remained viable after exposure to penicillin with streptomycin. The results were striking. While the original parent strain was highly resistant to streptomycin, the residual penicillin inhibited organisms were destroyed by small amounts of streptomycin. The reason for this apparent discrepancy is probably the fact that the streptomycin sensitive cells were present in comparatively small numbers in the original culture so that the action of streptomycin on them was obscured by the overwhelming numbers of resistant cells. Six *Str. viridans* strains were subjected to this treatment and all but one gave similar results, as can be seen from Table IV. While only a small number of bacterial strains were thus tested we believe the results obtained so far warrant the recording of these findings. If the *in vivo* action of the antibiotics parallels the action *in vitro*—and the consensus of opinion is that it does—it is possible that these findings may have a practical application in the treatment of subacute bacterial endocarditis. The administration of large doses of penicillin, if the invader is penicillin sensitive, with interruption of the penicillin treatment once in its early stage by a short course of streptomycin therapy might possibly shorten the course of the disease and lead to permanent clearing of the infection. This would have to be preceded by proper sensitivity tests of both the original infecting organisms as well as the penicillin residual cells. A simple method for testing penicillin residual bacteria with streptomycin is included in this paper.

The present methods for testing the susceptibility of bacteria to the action of penicillin are inadequate since their results are not indicative of the true response of the organisms to the drug. By diluting the culture for inoculation the cells capable of surviving large amounts of penicillin being present in comparatively small numbers, are eliminated by dilution so that a true cross section of the bacterial population is not represented. Besides organisms capable of withstanding high concentrations of penicillin are also inhibited by low concentrations of the drug, so that streaking plates to insure sterility may carry over in the loop sufficient penicillin to inhibit growth on the plate, thus obscuring the actual condition of the cultures. By destroying the penicillin with

penicillinase or by diluting the cultures so that the amount of penicillin left in them is negligible, viable organisms may be recovered, bacterial counts made of the surviving cells, and the size of the residuum of viable bacteria determined. Only in this way may the true condition of a bacterial culture, when exposed to the drug, be determined.

In the method of comparing the titer of sensitivity of a test organism with that of a standard, a hemolytic streptococcus strain is usually employed. The fallacy of this method is discerned when the susceptibility of a hemolytic streptococcus is compared with that of a *St. viridans* strain (See Tables II and III). Both are sensitive to the same degree according to the dilution method of testing. However, when the numbers of residual viable organisms found in each are compared, they can hardly be called equally susceptible to penicillin—23 per cent survivals in *St. viridans* as compared with 0.05 per cent in the hemolytic streptococcus. The finding of a highly in vitro sensitive strain of *St. viridans*, as tested by the present methods, in a case of subacute bacterial endocarditis, which responds poorly to penicillin treatment, becomes less baffling when the true character of such a strain is observed.

SUMMARY

Experiments are presented which show that penicillin is capable of destroying susceptible bacteria, by lysis or otherwise, under normal cultural conditions in amounts possible to maintain in the body of the patient.

The destructive action of penicillin on sensitive bacterial strains, however, is not complete even in high concentrations of the drug. A residuum of viable organisms always remains which is capable of withstanding the destructive action of the antibiotic but is inhibited from multiplying in its presence.

This inhibitory activity of penicillin on the residual viable cells extends through a wide range of concentrations so that large and small amounts of the drug have the same inhibitory effect on these remaining organisms.

The findings suggest that bacterial cultures do not constitute a homogeneous population but that individual members may possess different characteristics as to the manner of reaction under the influence of the antibiotic.

The inferences to be drawn from the results of the experiments in relation to the treatment of infectious diseases with the antibiotics are discussed.

We wish to thank Miss Anne Blevins of the New York Post Graduate Medical School and Hospital for her kindness in furnishing us with the *Streptococcus viridans* culture.

EFFECTS OF THE COLD PRESSOR TEST ON GLOMERULAR FILTRATION AND EFFECTIVE RENAL PLASMA FLOW

CAPTAIN PETER J. TALSO AND CAPTAIN ARCHIE R. P. CROSLY, JR., MEDICAL CORP.,
AND ROBERT W. CLARKE, PH.D.
FORT KNOX, KY

THE cold pressor test is a well-known method of determining the ability of the vasomotor system to respond to reproducible stimuli.^{1,4} Exposure of the hand or other body areas to ice water has been shown to cause pain, local vasoconstriction, and an elevation of arterial blood pressure.^{5,6} Recently attention has been drawn to the effects of a local cold stimulus on renal function. Diminished urinary volume, increased specific gravity, decreased urea clearance values, and reduced minute chloride output have been observed following moderately prolonged exposure to the stimulus of the cold pressor test in pregnant and nonpregnant women. Equivocal observations of these phenomena have been reported on other subjects.⁸ It is the purpose of this paper to report the effects of local peripheral cold on the specific renal functions of glomerular filtration and effective renal plasma flow.

METHODS

The subjects for these experiments were healthy white male volunteers between the ages of 18 and 37 years who on physical examination and urinalysis showed no evidence of renal disease. The men were asked to abstain from all solid food and liquids, with the exception of one glass of water at bedtime, after supper on the evening prior to the experiment.

On the morning of the experiment the subject assumed a reclining position. An indwelling soft rubber catheter (5.5 mm. in diameter) was installed in the bladder. Following the application of a blood pressure cuff to the left arm, intravenous infusions of isotonic saline were started in the veins of each forearm at a rate of 1 ml. per minute. The needle in the left arm was used for drawing blood samples, that in the right, for the administration of test substances. While these procedures were being carried out (a period of about one hour), the subject ingested 1 liter of water. Then a priming dose of 40 ml. of a 25 per cent mannitol solution* and 3 ml. of a 20 per cent sodium para-aminohippurate solution* was administered intravenously within a period of five minutes. This was followed immediately by a sustaining infusion consisting of a mixture of 600 ml. of isotonic saline, 100 ml. of a 25 per cent solution of mannitol, and 16 ml. of a 20 per cent solution of sodium para-aminohippurate at a rate of 4 ml. per minute. This rate was maintained throughout the experiment.

From Medical Department Field Research Laboratory
Received for publication Jan. 8, 1948.

*Obtained from Sharp & Dohme Inc., Philadelphia, Pa.

Zero time was established at thirty minutes after the beginning of the priming dose. Six or seven consecutive clearance periods, of approximately fifteen minutes each, were carried out. After the first two or three of these periods, which served as controls, the subject's left foot was immersed to the level of the malleoli in stirred ice water at 1°C and was kept there throughout one entire period. Following removal of the foot from the cold stimulus clearances were measured for three or four more periods.

Approximately five minutes after the beginning of each clearance period, blood samples were drawn through a three way stopcock attached to the needle in the left arm, care was taken to rinse out the system several times, using withdrawn and re-injected blood in order to wash out any residual saline. Time was noted, to the nearest tenth of a minute at the beginning and end of the drawing of each sample and the average was taken as the blood sampling time. At the end of each period the bladder was washed with 20 ml of saline and 20 ml of an

Fig 1—Representative experiment

Auscultatory blood pressures were obtained at least twice during each of the control periods as well as within thirty seconds before and after immersion of the foot in the ice water. During the period of immersion and in the two

§ Change from control (a) as ratio of all readings

|| Change from control (p) as ratio of all readings

following periods determinations were made at approximately two minute intervals. Thereafter the frequency of the readings was similar to that during the control periods.

Analyses for mannitol and sodium para aminosalicylate were carried out on heparinized plasma and on diluted urine samples according to the methods of Coicoran and Page⁹ and Smith and co workers¹⁰ respectively. It has been suggested that the clearance of mannitol may be slightly lower than the true glomerular filtration rate.¹¹ This would not alter the interpretation of these experiments since the importance of these data lies in their relative rather than in their absolute values.

RESULTS

The results of these experiments are summarized in Table I. A representative experiment is shown in Fig. 1. As will be noted in six out of seven subjects both glomerular filtration rate and effective renal plasma flow decreased either during the application of the cold stimulus or within approximately thirty minutes thereafter. In no subject did the effect persist longer. The average decreases in glomerular filtration rate and effective renal plasma flow as compared with the controls were 14 per cent and 21 per cent respectively. The observed depression of urine flow confirms the finding of Odell and Aragon.

In all subjects the blood pressure rose promptly after application of the cold stimulus and this rise was sustained throughout the period of immersion. Upon removal of the stimulus the blood pressure gradually decreased returning to control levels in fifteen to twenty minutes. Examination of these data reveals no correlation between the degree of blood pressure elevation and the observed changes in renal function.

DISCUSSION

The application of a peripheral cold stimulus is found to decrease urinary minute volume, glomerular filtration rate and effective renal plasma flow.

The large reduction of urine flow as compared with the moderate depression of glomerular filtration rate is regarded as evidence of alteration in the tubular reabsorption of water. This antidiuretic response may be of the same nature as that demonstrated by Rydin and Verney in dogs subjected to emotional stress.¹²

The results obtained on Subject 3 (26 years of age) may be of interest. While the blood pressure rose in all experiments as a result of the stimulus the rise was not associated with changes in glomerular filtration and renal plasma flow in this one subject. The initial diastolic blood pressure (128/90) together with the blood pressure response (164/116) during exposure to cold would suggest according to the criteria of Hines and Brown¹³ that this individual belongs to the prehypertensive group. However as indicated above these observations do not establish a correlation between the degree of blood pressure rise and the changes in renal function in response to the cold stimulus.

The mechanisms ultimately responsible for these findings remain to be identified and are being investigated.

SUMMARY

Studies were made of the effects of the cold pressor test on renal function. Seven male volunteers who had no history of renal disease served as subjects. Glomerular filtration (as measured by mannitol clearance) and effective renal plasma flow (as measured by sodium para-aminohippurate clearance) were determined before, during, and after immersion of the foot in ice water at 1° C for fifteen minutes.

In six out of seven subjects both glomerular filtration rate and effective renal plasma flow decreased either during the application of the cold stimulus or within approximately thirty minutes thereafter. In no subject did the effect persist longer. The average decreases in glomerular filtration rate and effective renal plasma flow, as compared with the control values, were 14 per cent and 21 per cent, respectively.

RELATION BETWEEN STRUCTURAL AND FUNCTIONAL ALTERATIONS OF THE LIVER

MURRAY FRANKLIN, M D, HANS POPPER M D, P H D, FREDERICK STEIGMANN, M S, M D, AND DONALD D KOZOLL M S, M D
CHICAGO ILL

A CORRELATION between basic histopathologic phenomena in the liver and the results of the different liver function tests is still not established. In the past, repeated attempts to secure such a correlation were primarily based upon animal investigations with experimentally produced well defined conditions.¹⁻⁴ In the human being, several approaches were attempted. One approach was the comparison between the histologic picture found in autopsy material and the results of liver function tests carried out shortly before death. This is objectionable because of the marked changes which occur during the agonal period.⁵ Another approach was the performance of serial function tests during the course of a disease with well established histologic pictures as for example infectious hepatitis or obstructive jaundice.⁶⁻⁹ Only recently has a systematic attempt been made to compare the results of function tests with the histologic picture seen in biopsies.¹⁰⁻¹² In the following study, utilizing a relatively large series of cases of different diseases a statistical attempt has been made to compare morphologic phenomena, independent of the underlying disease with the results of liver function tests carried out at the time of the biopsy. The utilization of a larger material appeared desirable to overcome the obvious overlapping caused by the occurrence of more than one of the basic histologic phenomenon in a given case.

A statistical correlation between morphologic alterations and the results of liver function tests was carried out to study the following two problems:

1. Evaluation of different liver function tests by comparison of their results with the presence and degree of liver cell damage
2. Functional significance of the different basic morphologic phenomena

MATERIAL AND METHODS

Patients suffering from various stages of different liver diseases or hepatomegalies make up the material of this study. The liver diseases studied include acute infectious and toxic hepatitis, extrahepatic biliary obstruction due to tumor or stone, different types of cirrhosis and a miscellaneous group which included such conditions as amyloidosis, Boeck's sarcoid, lymphosarcoma, xanthomatosis and so on. A total of one hundred sixty five biopsies which included thirty five repeat biopsies on the same patients was performed and the histologic findings were statistically correlated with the results of a series of function tests carried out within two days of the biopsy. All function tests were not carried out in every case. The biopsies in the great majority of cases were performed by means of the Turkel needle¹³ utilizing the lateral approach through the seventh to tenth right costal inter space. In a few

instances they were performed during laparotomy. The biopsy material was fixed in Zenker formalin or Carnoy's solution. Sections were stained with hematoxylin-eosin, Mallory's aniline blue connective tissue stain, and Gomori's reticulum fiber stain. The following histopathologic phenomena were correlated with results of liver function tests: (1) diffuse liver cell damage, (2) focal necrosis, (3) regeneration, (4) distorted reconstruction, (5) per portal inflammatory activity, (6) fatty metamorphosis, and (7) increased Kupffer cell activity.

A tetrachoric coefficient¹⁴ of correlation of these phenomena with results of the biochemical determination was chosen for statistical correlation. By this method one is enabled to correlate the presence or absence of one variable (histopathologic phenomena) with the presence or absence of a second variable (abnormal result of function test). The coefficient, when corrected for the number of cases, yielded a critical ratio (CR). This mathematical figure (CR) indicates the degree to which the obtained results represent a reliable or consistent trend. A critical ratio above 2 is considered significant. The formula employed and an example in the derivation of a CR value follows:

$$CR = \frac{ad - bc}{\sqrt{(a+b)(c+d)(a+c)(b+d)}} - \frac{1}{\sqrt{N}}$$

Variable 2	Variable 1				Focal Necrosis	Sedimentation Rate		
	+	-	+	-		Abnormal	Normal	Total
Present	a	b	c	d	Present	53	37	90
Absent	e	f	g	h	Absent	24	20	44
	a + e	b + f	c + g	d + h		77	57	134

$$CR = \frac{1060 - 888}{\sqrt{16,984,440}} - \frac{1}{\sqrt{134}} = +0.482$$

For use in scatter graphs the pathologic phenomena were subjectively graded from 1 plus to 4 plus.

Limits between normal and pathologic results of each of the applied function tests were arbitrarily drawn (Table I). In general, the borderline of the pathologic levels chosen is the one currently accepted. In some instances, however, the borderline has been set higher than that usually employed since only the markedly pathologic levels were expected to show a correlation. This was especially true in the case of total serum bilirubin and also cholesterol ester ratio, prothrombin time, and sedimentation rate. For serum alkaline phosphatase two levels were selected: 4 to 10 Bodansky units as found as a rule in liver cell damage, and

TABLE I FUNCTION TESTS AND LEVELS ARBITRARILY SELECTED FOR CORRELATION WITH HISTOPATHOLOGIC PHENOMENA

Serum total protein	Below 6 Gm %
Albumin/globulin ratio	Below 1.0
Serum nonprotein nitrogen	Above 35 mg %
Cephalin cholesterol flocculation	+++ and ++++ ¹⁶
Thymol turbidity	Above 4 units ^{17, 18}
Total serum cholesterol	Above 250 mg %
Percentage of cholesterol ester in total serum cholesterol	Below 45% ^{19, 20}
Serum alkaline phosphatase	Above 10 BU ²¹
Total serum bilirubin	Above 8 mg % ²²
Bromsulfalein retention (5 mg/kg in 45 min)	Above 10%
Urinary urobilinogen	Above 3 Ehrlich units ²³
Stool urobilinogen	Below 10 Ehrlich units ²³
Prothrombin time	Below 80% ²⁴
Serum vitamin A	Below 15 µg ²⁵
Sedimentation rate	Above 30 mm/hr

above 10 unit as found usually in extrahepatic biliary obstruction. Decreased pathological values of urinary urobilinogen were not utilized in this study. However a reduction of stool urobilinogen to below 10 units was considered evidence of biliary obstruction and was used in the statistical correlation. The level selected for serum vitamin A was quite low. Abnormal elevation of vitamin A was not found in this series.

RESULTS

Diffuse liver cell damage (Fig 1 A) was considered to be present when all or almost all liver cells revealed one or more of the following aberrations from the normal: disorganization of the liver cell cords; unusual variation in size of the cells; hazy borders; irregular staining of the cytoplasm with appearance of irregularly shaped vacuoles (apparently not containing fat); clumping of cytoplasm with marked basophilia of the clumped material; eosinophilic coagulation necrosis; irregular size, shape and staining of the nuclei leading to pyknosis.

A

B

Fig 1—Photomicrographs of liver biopsy specimens. A: Diffuse liver cell damage in a case of infectious hepatitis. Cytoplasm and nuclei of the liver cells vary in size and staining qualities. The outline of the cells is hazy and the architecture of the cord is irregular. B: Focal necrosis in a case of cholecystitis. The liver cells have a normal appearance. In small areas they are necrotic and are replaced by polymorphonuclear leucocytes which accumulate in the perisinusoidal spaces.

or ballooning of the nuclei (glycogen nuclei) and hyalinization of the entire cell. These changes varied in intensity throughout the lobule but some degree of damage was present in the entire lobule.

As seen from Table II there was a statistically significant correlation between liver cell damage and cephalin-cholesterol flocculation, thymol turbidity, albumin/globulin ratio and bromsulfalein retention. A less significant relation was found to marked decrease in prothrombin, high values of serum bilirubin and slightly elevated levels of alkaline phosphatase (4 to 10 Bodansky units). Levels of alkaline phosphatase above 10 units showed little correlation

TABLE II CORRELATION BETWEEN MORPHOLOGIC PHENOMENA AND PATHOLOGIC RESULTS OF LIVER FUNCTION TESTS AS EXPRESSED BY THE CRITICAL RATIO (A RATIO ABOVE +2 INDICATES A SIGNIFICANT RELATION)

Sedimentation rate	+0.02	+0.48	+0.16	+2.77	+2.95	-0.51	-4.63

as did the results of the alkaline phosphatase when taken as a whole. There was no relation between histologically recognizable parenchymal damage and abnormal levels of total protein, urinary urobilinogen, decrease in cholesterol ester ratio, elevated nonprotein nitrogen, and sedimentation rate.

Among the scatter graphs which plot the quantitative relation between liver cell damage and the results of various liver function tests, three appear particularly instructive. No quantitative relation was found between parenchymal damage and total serum protein levels (Fig. 2), except at very low values (cases of hypoproteinemia due to causes other than liver disease were not included in this study). The degree of morphologic damage associated with total protein levels between 5 and 8 per cent was similar. However, there was an inverse quantitative relation between the albumin/globulin ratio and the degree of parenchymal damage (Fig. 3). The relation between liver cell damage and cephalin cholesterol flocculation is more complicated (Fig. 4). The plotted (composite) curve shows that the degree of liver cell damage is proportional to the cephalin-cholesterol flocculation between the ranges of 1 plus and 4 plus. However, a greater degree of damage coincided with cephalin-cholesterol flocculation values of 0 than those of 1 plus. The explanation for this may lie in the fact that many patients with negative cephalin-cholesterol flocculation had extrahepatic biliary obstruction secondary to tumor or lithiasis and some of these morphologically exhibited marked liver cell damage. On the other hand, most of the cases in the 1 plus to 4 plus range had primary hepatitis or cirrhosis.

Focal necrosis (Fig. 1, B) was indicated by small, irregularly scattered areas in which the parenchymal liver cells were either absent or present in the form of small anuclear fragments. They were replaced by large numbers of round

Fig 2—Relation between serum total proteins and liver cell damage

Fig 3—Relation between albumin/globulin ratio and liver cell damage

cells or polymorphonuclear leucocytes giving these areas a rather cellular appearance. No definite correlation between focal necrosis and any of the function tests was found.

Regeneration of liver cells (Fig 5, A) was characterized by large parenchymal cells often containing more than two nuclei which were frequently bizarrely shaped. These regenerating cells were found either in protracted liver cell damage or in apparent recovery from a preceding injury. This morphologic phenomenon showed a correlation only with elevated levels of the thymol turbidity test.

Fig 4—Relation between cephalin cholesterol flocculation and liver cell damage

Fig 5—Photomicrographs of liver biopsy specimens. A Marked liver cell regeneration in a case of chronic infectious hepatitis. The liver cells in general reveal little damage but some of them are large and have two or three nuclei and abundant cytoplasm. There is some proliferation of histiocytic cells. B Distorted reconstruction in a case of portal cirrhosis (Mallory's aniline blue stain). Small nodules devoid of the usual lobular architecture are separated by wide connective tissue trabeculae.

Distorted reconstruction of the liver parenchyma (Fig 5 B) denoted partial or complete loss of the lobular pattern with replacement by parenchymal nodules, the cells of which were not arranged around a central vein. These pseudolobules varied in size, were often found near the periportal field and were usually well demarcated by more or less dense connective tissue trabeculae.

Fig. 6.—Photomicrographs of liver biopsy specimens. A: Periportal inflammatory activity. There is dense lymphocytic and histiocytic infiltration of the widened periportal field. The inflammatory exudate is arranged around lymphatics. There is some proliferation of the septal bile ducts. B: Fatty metamorphosis in a case of acute toxic hepatitis. Large fat droplets replace the cytoplasm of most of the liver cells. C: Kupfer cell mobilization (high power). The liver cells reveal normal appearance. The Kupfer cells are separated from the liver cell cords. They are large and bulge forward into the sinusoids.

This phenomenon occurred in cirrhosis. Distorted reconstruction revealed significant correlation with cephalin-cholesterol flocculation and a less significant one with thymol turbidity and sedimentation rate.

Periportal inflammatory reaction (Fig 6, A) described inflammatory changes in the portal triads usually originating in and around the lymphatics. These changes were characterized by accumulations of round cells and only rarely of polymorphonuclear leucocytes. The cellular accumulations varied in size and shape. Proliferation of septal bile ducts was frequently associated with the more marked of these inflammatory changes. The reaction showed a significant relation to increased sedimentation rate and only a minor one to the cephalin-cholesterol flocculation test.

Fatty metamorphosis (Fig 6, B) was characterized by accumulation of fat in the liver cells in the form of various sized droplets. There appeared to be no significant relation between these fatty changes and any of the function tests.

Increased Kupffer cell activity (Fig 6, C) denoted their mobilization and proliferation. This was characterized by an increase in the number and an enlargement of the individual Kupffer cells. They were separated from the liver cell cords and their abundant cytoplasm extended into the lumen of the sinusoids and often contained phagocytosed material. This picture showed a significant correlation with the albumin/globulin ratio and with a marked increase in serum bilirubin.

COMMENT

In the interpretation of the correlations found, it must be kept in mind that they are statistical and association must not be confused with causation. The fact that a morphologic phenomenon may be associated with abnormal values of a certain function test is no proof that the abnormal function is caused by that pathologic change. Some common factor might be responsible for both morphologic change and functional alteration.

As expected, diffuse liver cell damage revealed, in general, a good correlation with many of the liver function tests. In some instances, however, liver function tests were negative in the presence of visible liver cell damage. Moreover, in individual cases there were various combinations of positive liver function tests. The pattern of these variations is only partly known. Thus the cephalin-cholesterol flocculation test was almost invariably negative in uncomplicated extrahepatic biliary obstruction.

Focal changes, though morphologically often far more impressive than generalized liver cell damage (the recognition of which is not always a simple matter), are not necessarily associated with liver function impairment. The bulk of the still intact liver parenchyma compensates for the relatively few cells which are destroyed. This observation is well in keeping with the widespread occurrence of focal necrosis in a multitude of diseases in which no functional liver impairment is found. Hence, conclusions concerning the extent of liver cell damage should not be drawn from isolated though anatomically impressive alterations.

Fatty changes as such do not interfere markedly with liver function. Distorted reconstruction as an expression of cirrhosis is related to some but not to all of the function tests. Except for the thymol turbidity test there is no statistically recognizable relation between regenerative processes and any of the function tests. The increased Kupffer cell activity in cases of severe jaundice is probably best explained by the large amounts of bile pigment in them. The inflammatory nature of the portal reaction explains its correlation with the elevation of the sedimentation rate, however, no relation to other function tests was demonstrated.

The evaluation of the various function tests by a morphologic method rendered, in general, results similar to those of other methods.^{6, 28} In contrast, however, to the findings of Sherlock¹⁰ this method failed to reveal a significant correlation between total serum protein concentration and any of the examined pathologic phenomena. The albumin/globulin ratio appeared to be a much better index of liver cell damage. The total protein concentration without albumin/globulin partition is no indicator of liver cell damage except when markedly decreased. With marked liver cell damage the albumin/globulin ratio may be reversed with normal total protein values. This is partly explained by reduced formation of albumin by the damaged liver. The demonstrated correlation between Kupffer cell mobilization and the albumin/globulin ratio is probably due to hyperglobulinemia which is known to occur with stimulation of the reticuloendothelial system.²⁹ The nonprotein nitrogen appears to be unrelated to any of the examined phenomena. Elevation of nonprotein nitrogen and urea nitrogen in liver disease (in some forms of hepatitis and in prolonged extrahepatic biliary obstruction) is primarily a renal phenomenon due to pathologic reabsorption of urea in the renal tubules.^{30, 31}

The cephalin cholesterol flocculation revealed a good correlation with liver cell damage since in the absence of parenchymal damage the cephalin flocculation is almost invariably negative. This observation obtained by statistical evaluation of the entire material must be qualified when individual cases are analyzed. The cephalin cholesterol flocculation is usually negative in uncomplicated extrahepatic biliary obstruction, even if severe liver damage is visible under the microscope. With equal degrees of morphologically demonstrable liver damage the cephalin cholesterol flocculation is pathologic in primary hepatitis (infectious or toxic) or in cirrhosis and normal in an uncomplicated biliary obstruction due to tumor or stone. If the biliary obstruction is complicated by bacterial infection of the portal triads the cephalin cholesterol flocculation becomes positive.¹² The aforementioned characteristics of the cephalin-cholesterol flocculation test make it especially useful from a practical diagnostic standpoint.^{3, 3} No explanation can be offered for the fact that a test which depends on the relation between albumin and gamma globulin was negative in prolonged uncomplicated biliary obstruction despite advanced liver cell damage. The fact that this test is usually positive in cirrhosis accounts for its close correlation with distorted reconstruction of the lobular pattern.

The thymol turbidity reveals statistically the most significant correlation with liver cell damage. The close correlation with regeneration agrees with

observations that this test remains positive in infectious hepatitis longer than the other tests. Based on this, Kunkel and Hoagland³⁶ associated the thymol turbidity with regeneration. Necfe,³⁷ however, connected it with periportal infiltration, with which we found no correlation. Whether the thymol turbidity is an expression of regeneration also in the early stages of infectious hepatitis is as yet unsettled. Its relation to reconstruction can be interpreted similarly to that of the cephalin-cholesterol flocculation test.

The total serum cholesterol and cholesterol ester fraction showed no significant correlation with any of the examined morphologic alterations. The total cholesterol elevation in surgical jaundice is probably due to obstructed bile flow. Cholesterol ester reduction in the material studied appeared too erratic to be statistically significant.

Elevation of serum alkaline phosphatase in general showed no relation to the studied morphologic changes. However, if the results of the alkaline phosphatase tests are broken down, the group between 4 and 10 Bodansky units revealed a relation to liver cell damage but not the group above 10 Bodansky units. Marked elevation of the alkaline phosphatase level is considered primarily the result of retention of the enzyme due to interference with biliary excretion,³⁸ since it occurs chiefly in cases of surgical jaundice, thus accounts for the absence of relation to liver cell damage. In the group with values between 4 and 10 units, medical jaundice predominated. This level might be explained by a lesser degree of bile flow interference or, as has been claimed, by an increased formation by the damaged liver cells.^{38, 41}

Bromsulfalein retention (studied only in nonjaundiced patients) was related only to liver cell damage. Elevation of urinary urobilinogen was usually absent without liver damage. On the whole, however, in the applied approach they could not be correlated with each other since in the presence of biliary obstruction (intra- or extrahepatic) urobilinogen may be absent from the urine despite marked liver cell damage. Stool urobilinogen being primarily an indicator of biliary excretion showed no relation to the studied phenomena.

The close relation of reduction of prothrombin to liver cell damage is due to the fact that in the absence of parenchymal damage the prothrombin time was invariably normal. However, the reverse did not hold true, that is, the prothrombin time was occasionally normal in spite of histologically recognizable cell damage. As generally accepted a pathologic prothrombin time is evidence of liver function impairment, provided other causes of hypoprothrombinemia such as poor vitamin K absorption due to obstructed bile flow or intestinal disorders are ruled out.

The reduction of the plasma vitamin A level showed a fair relation to liver cell damage in that when low values were found in liver disease the parenchymal cells almost constantly appeared damaged. Low vitamin A levels have been considered a test for impaired hepatic function.^{2, 40, 43} Obviously the reduction can also be caused by other factors leading to endogenous vitamin A deficiency. This explains why in some instances without liver cell damage low vitamin A values were found.

The sedimentation rate revealed a correlation with periportal activity, probably because of the latter's inflammatory character. The correlation of the sedimentation rate with distorted reconstruction of the lobular pattern may stem from the fact that cases of active cirrhosis showing such reconstruction usually exhibit inflammatory periportal activity.

In general, the presented correlations may aid in the differential diagnosis of liver disease by a morphological evaluation of the function. An association between function tests and morphologic alterations even without causative connection, is significant.

SUMMARY

In one hundred thirty patients (thirty five repeatedly studied) suffering from various liver diseases the histologic picture of the liver as seen in biopsy specimens obtained by aspiration or laparotomy was compared with the results of a series of liver function tests performed at the time of biopsy.

The incidence of seven morphologic phenomena (diffuse liver cell damage, focal necrosis, regeneration, distorted reconstruction, periportal activity, fatty metamorphosis, and Kupffer cell mobilization) was compared statistically with the results of each of different liver function tests.

A significant correlation was found between diffuse liver cell damage and albumin/globulin ratio, cephalin cholesterol flocculation, thymol turbidity, and bromsulphalein retention, a lesser degree with highly elevated serum bilirubin, reduced plasma vitamin A, increased prothrombin time and slightly elevated alkaline phosphatase. No correlations were elicited between parenchymal damage and total serum protein, total cholesterol, cholesterol ester ratio, urinary urobilinogen, stool urobilinogen, alkaline phosphatase in general (and markedly elevated alkaline phosphatase specifically), nonprotein nitrogen, or sedimentation rate.

Focal necrosis, in contrast to diffuse liver cell damage, was not associated with significant changes in liver function. The same was found with fatty metamorphosis.

Regeneration showed a correlation with increased thymol turbidity. Distorted reconstruction of the lobular pattern (as seen in cirrhosis) was related to cephalin cholesterol flocculation, thymol turbidity, and elevation of sedimentation rate. Kupffer cell activity appeared related to elevated serum bilirubin and pathologic albumin/globulin ratio.

These findings provided a basis for the morphologic evaluation of various liver function tests and a discussion of the functional significance of the aforementioned pathologic phenomena.

THE IMPORTANCE OF THE RATE OF DYE REMOVAL IN THE BROMSULFALEIN TEST OF LIVER FUNCTION

CAMPBELL MOSES, M D , FRANCES H CRITCHFIELD, M S , AND
THEODOR B THOMAS, M D
PITTSBURGH, PA

FOLLOWING the introduction of bromsulfalein (BSP) retention as a test of liver function by Rosenthal and White¹ in 1925, numerous attempts have been made to improve the clinical method. Currently, the accepted procedure for the test is that recommended by Mateer and co-workers². This procedure uses intravenously 5 mg of BSP per kilogram body weight and accepts 4 per cent retention in forty-five minutes as the upper limit of normal liver function. The BSP concentration in serum is determined by the method of Gaebler.

Several years ago MacDonald³ published clinical evidence indicating the value of serial BSP determinations in the detection of liver damage. By taking blood samples at frequent intervals after the injection of 5 mg per kilogram of BSP intravenously, he was able to detect liver damage not evident from a single forty-five minute blood sample. The study here reported was undertaken to compare the value of the fifteen-minute blood sample with the forty-five minute sample in the detection of liver damage.

EXPERIMENTAL OBSERVATIONS

There is abundant evidence that intravenously injected BSP is not quantitatively excreted in the bile but is eliminated by other systems of the body, particularly the reticulo-endothelial system^{4, 5, 6, 7, 8}. After determining in preliminary experiments in dogs that 5, 10, and 20 mg per kilogram of BSP intravenously yielded reproducible and quantitatively similar curves, the effect of blocking the reticulo-endothelial system with India ink was studied. Fig 1 records a typical experiment. It will be noted that, although within 48 hours after the injection of the India ink the forty-five minute serum BSP level was below 1 mg per cent (10 per cent retention), as long as 192 hours later the fifteen-minute serum concentration remained above the control level.

Following splenectomy (Fig 2) with removal of this portion of the reticulo-endothelial system, there was a temporary increase in BSP retention. As illustrated in Fig 2, this retention was evident in the fifteen-minute serum sample two days after the forty-five minute sample had returned to control levels.

After obtaining a control BSP retention test using 5 mg per kilogram intravenously, hepatic damage was produced in rabbits by giving 0.5 ml per kilogram of carbon tetrachloride in corn oil via stomach tube. BSP retention was tested two days and ten days after the administration of carbon tetrachloride. Table I records the marked BSP retention that occurred in the fifteen minute serum sample long after the forty-five minute sample had returned to control levels.

The results of these experiments indicated that, when the reticulo-endothelial system was compromised (India ink injection, splenectomy) or when

Fig 1

Fig 2

TABLE I PERCENTAGE OF BROMSULFALEIN RETENTION

RABBIT NO	CONTROL		TWO DAYS AFTER CCL ₄		TEN DAYS AFTER CCL ₄

hepatic change was produced by the oral administration of carbon tetrachloride the fifteen minute serum BSP sample reflected the change long after the forty five minute sample had become normal

CLINICAL OBSERVATIONS

BSP determinations using Gaebler's method² and 5 mg per kilogram doses in twenty individuals with normal liver function are recorded in Table II. Table III includes the BSP retention data from twenty one individuals hospitalized with miscellaneous disorders.

All the normal individuals (Table I) had a fifteen minute BSP serum concentration below 25 per cent. This finding agrees with the observations of MacDonald⁴ who reported more than 25 per cent retention in fifteen minutes in only three of thirty eight patients. In Patients 1, 7, 8, 9 and 21 in Table III

TABLE II BROMSULFALEIN RETENTION IN INDIVIDUALS WITH NORMAL LIVER FUNCTION

20	Control (technician)	F	23	16	4

(all of whom had some evidence of hepatic disease) the forty-five minute sample was within Mateer's upper normal limits of 4 per cent retention, although the fifteen-minute sample revealed more than 25 per cent BSP retention.² Attention is called particularly to Patient 21 with congestive heart failure. In our experience, increased BSP retention in the presence of congestive heart failure is likely to be more evident in the fifteen-minute than in the forty-five minute sample. The decrease in BSP retention that occurs with recovery from congestive heart failure, demonstrated here, has been repeatedly observed.

TABLE III BROMSULFALEIN RETENTION IN INDIVIDUALS HOSPITALIZED WITH MISCELLANEOUS DISORDERS

PATIENT	DIAGNOSIS	SEX	AGE (yr)	BROMSULFALEIN RETENTION (%)		COMMENTS

Table IV records the BSP retention of seventeen chronic alcoholics hospitalized for acute intoxication. At the time of admission to the hospital the BSP retention in forty five minutes was 4 per cent or under in five cases. However, the fifteen minute sample revealed 30 per cent or more BSP retention in every instance.

With abstinence from alcohol, and with sedation as necessary (chloral hydrate, paraldehyde) and an adequate dietary regimen there was a distinct decrease in BSP retention in every case. The decrease in BSP retention was particularly striking in the fifteen minute sample in Cases 1, 3, 4, 6, 10, and 13 which had exhibited only slight increases in BSP retention before the inception of therapy.

Six of these individuals (Cases 1, 5, 7, 13, 15, 17) received only the routine hospital diet without a high protein diet or vitamin supplements. The eleven other subjects received daily a high protein diet (120 Gm or more), 6 Gm of

choline dihydrogen citrate in divided doses, and 6 capsules each containing 110 mg ascorbic acid, "d" calcium pantothenate 9.5 mg, choline chloride 20.5 mg, folic acid 5.5 mg, inositol 54.5 mg, niacinamide 110 mg, pyridoxine HCl 10 mg, riboflavin 13.0 mg, thiamin HCl 16.5 mg, and liver powder 220.0 milligrams*.

In this experiment, improvement in liver function as evidenced by a decrease in BSP retention occurred both in those patients receiving the high protein diet with supplements and in those receiving the routine hospital diet without choline and vitamin supplements. Although the clinical impression obtained that the patients on the high protein, high vitamin regime responded more rapidly, no conclusive evidence in this regard was observed.

SUMMARY

These data indicate that sufficient additional information is obtained from the fifteen-minute serum sample in the BSP retention test to justify its use along with the forty-five minute sample.

It is suggested that with the BSP method used in this study 25 per cent retention in the fifteen-minute sample is probably the upper limit of normal. As noted by Mateer and associates,² 4 per cent retention marks the upper limit of normal in the forty-five minute sample.

The decrease in BSP retention following recovery from acute intoxication in a group of chronic alcoholics is reported. This decrease in BSP retention was not markedly different in patients receiving the routine hospital diet from those receiving a high protein diet with choline and vitamin supplements.

THE EFFECT OF ORAL ADMINISTRATION OF CASEIN HYDROLYSATE ON THE TOTAL CIRCULATING PLASMA PROTEINS OF MAN

BACON F CHOW PH D AND SHIRLEY DeBIASE
NEW BRUNSWICK, N J

NUMEROUS investigators report that diseases and physical injury can effect not only a decrease in plasma protein concentration but also a change in the composition of the plasma proteins¹⁻⁶. The outstanding changes common to many of these situations are a decrease in the per cent of albumin and an increase in the per cent of alpha globulins such as are commonly observed in protein depletion⁷⁻⁹. Consequently, the changes in the plasma protein patterns in many situations may be due to protein depletion rather than to an inherent specificity of a given disease. Should this be the case in fact then the feeding of a suitable protein should result in a return toward normal of the plasma protein pattern without the necessity of effecting at the same time any significant change in the disease itself. Some selection of the protein may be necessary since it would appear that different proteins may cause regeneration of different plasma proteins to different degrees¹⁰⁻¹¹.

The ability of a protein or a hydrolysate of a protein to stimulate the regeneration of various plasma proteins has some importance in itself, since hydrolysates have come into clinical use¹⁻¹⁴. The present investigation is concerned with a study of the plasma protein pattern in a variety of clinical cases and with the ability of a casein hydrolysate* used as the sole source of protein to cause restoration of abnormal patterns to normal.

EXPERIMENTAL METHODS

Plasma volumes were determined by the method of Høegh and Stewart¹⁵ using Evans blue dye (T 1524). The total protein concentration of plasma was determined by the micro Kjeldahl method with selenium and copper sulfato as catalysts. For electrophoretic analysis of the plasma proteins about 10 ml of plasma were diluted with an equal volume of diethylbarbiturate buffer at pH 8.4 and ionic strength of 0.1 and then dialyzed against 2.0 liters of the same buffer for twenty four hours in a cold room. The scanning technique and the method of resolution of Longsworth¹⁶ were used.

Chemical and Biologic Characteristics of the Hydrolysate Used—The characteristics of the casein hydrolysate used in these studies were determined because a protein or protein hydrolysate would be expected to regenerate plasma protein only if it contains the essential amino acids in adequate proportions as evidenced by chemical analysis and by ability to support nitrogen balance

and to promote growth of young animals at a low total dosage. The essential amino acid content of the hydrolysate is given in Table I. The streptogenin content, the nitrogen balance index as observed in dogs and the growth efficiency obtained in rats are given in Table II.

These data demonstrate that the hydrolysate used is equal to a high grade of edible casein in nutritive properties, casein itself being an adequate protein for most nutritive purposes. This view is also borne out by comparative feeding of casein and this hydrolysate to protein depleted rats²¹ and by its ability to support nitrogen balance in man at a level of 0.18 to 0.20 Gm. nitrogen per kilogram per day.¹⁸

RESULTS

The determination of the ability of casein hydrolysate to promote plasma protein regeneration and the estimation of the type of plasma protein regenerated were made by feeding experiments wherein the casein hydrolysate was administered to two groups of hypoproteinememic patients, a total of twenty-eight subjects. Dextrimaltose was given so that the daily energy intake of the patients was at least 3,000 calories. The plasma protein concentration and electrophoretic

*The authors are indebted to Dr. Paul R. Cannon and associates for the determination.

analyses were performed on samples of plasma taken before and after two to four weeks of administration. The patients in Group I as a whole were hypoproteinemic* and not hypoalbuminemic, and the albumin globulin ratios were essentially normal. Therefore in order to study the effect of casein hydrolysate feeding then total circulating plasma proteins were determined before and after the hydrolysate feeding period. The patients in Group II were not only hypoproteinemic but also markedly hypoalbuminemic. The albumin globulin ratio of the plasma was considerably below normal in all patients. Hence the increase of albumin content following the administration of casein hydrolysate was marked. The other components of the plasma protein were also determined before and after the hydrolysate therapy.

Group I The Increase of Total Circulating Proteins Following the Oral Administration of Casein Hydrolysate to Hypoproteinemic Patients—Casein hydrolysate was fed to three patients after hemiotomy at a low level of nitrogen intake (0.2 Gm. nitrogen per kilogram body weight per day) for about two weeks (Table III). These patients though in nitrogen equilibrium, were unable to increase their circulating plasma protein. Two other patients after hemiotomy were fed at a moderate level of nitrogen intake (0.5 and 0.6 Gm. nitrogen per kilogram body weight per day). A pronounced increase of plasma proteins was observed in both patients. Subsequent studies used a high dosage level ranging from 0.6 to 1.0 Gm. nitrogen per kilogram body weight per day for periods ranging from ten days to seven weeks.

Total circulating proteins of fifteen patients characterized by different types of disease were determined before and after hydrolysate feeding (Table IV). An increase of at least 15 per cent in plasma protein was obtained in ten of the fifteen patients. An increase of somewhat more than 10 per cent the limit of accuracy of the estimation was observed in the remaining five. This increase involved both albumin and globulin fractions in all subjects but one. Patient An J. Hydrolysate feeding did not produce any consistent or significant changes in the per cent of any particular globulin fractions.

kilogram body weight per day. The patients in this series were divided into two groups. Subgroup A six subjects responded to the hydrolysate therapy and subgroup B five subjects failed to respond to the casein hydrolysate feeding; the latter were all in the terminal stages of their diseases.

Subgroup A. The results given in Table V demonstrate that administration of this hydrolysate brought about a rapid increase in plasma protein concentration or in plasma volume in all patients but one (Patient Lo). The plasma volume of Patient Eg was not determined; therefore its change if any is not known. The albumin content in terms of gram per cent was increased in all cases. As would be expected, the increase was most marked where hypoalbuminemia and hypoproteinemia were most severe; that is, where albumin globulin ratio and plasma protein concentration were the lowest.

The response of Patient Lo to the hydrolysate therapy is of particular interest because there was neither increase in protein concentration nor in plasma volume after sixty-eight days of the hydrolysate therapy. Nevertheless there was a very significant increase in albumin globulin ratio. The increase in albumin therefore was made at the expense of the globulins.

Subgroup B. Four hypoalbuminemic patients with albumin content of 30 per cent or less were fed with casein hydrolysates at a level of as much as 0.6 Gm nitrogen per kilogram body weight per day for about two weeks or longer. During this period the patients were in positive nitrogen balance and retained as much as 0.4 Gm nitrogen per kilogram body weight per day. However in spite of the large nitrogen retention the pattern of the plasma proteins of these patients failed to approach normal (Table VI). The albumin globulin ratio remained low and there was no significant change in the total circulating albumin or globulins. No one of these four patients who did not respond to the therapy survived for any great length of time following these observations. The results may indicate that during the advanced stages of certain diseases patients may be unable to utilize an otherwise adequate mixture of amino acids and polypeptides for the synthesis of plasma proteins.

DISCUSSION

The patients used in this study reacted much the same as do experimental animals to gradual protein depletion. Consequently results are consistent with the belief that of the systemic manifestations of diverse diseases the abnormalities observed in the pattern of the plasma proteins and in their amount are in part the results of a general protein deficiency.

A casein hydrolysate which contains all the essential amino acids and high biologic values as determined in laboratory animals and in man was administered to patients to correct the abnormal plasma patterns. The patients used constituted a rather heterogeneous group. They were characterized by different degrees of hypoproteinemia and by different types of disease; in addition the period of hydrolysate therapy was not always uniform. However in spite of these variations the results are sufficiently striking to indicate that in general the administration of a suitable casein hydrolysate at a sufficiently high level to hypoalbuminemic patients results initially in a rapid increase in plasma

albumin content. Such a result is not to be expected in the terminal phases of certain diseases. When the hypoalbuminemia is not severe, the feeding of casein hydrolysate produces an increase of both plasma albumin and of plasma globulin. This effect on the globulin fractions may have special significance because of the possible relationship of certain globulins and certain of the so-called vital functions of the body related to the synthesis of certain of the hormones, the enzymes and the antibodies.

The failure of some patients to regenerate either albumin or globulins following casein hydrolysate therapy in spite of positive nitrogen balance is of interest. This fact is in line with other information which indicates that plasma proteins are not as readily synthesized as some other tissue proteins.

SUMMARY

Casein hydrolysate has been given to twenty-eight hypoproteinemic and hypoalbuminemic patients with a variety of diseases. It promotes the regeneration of both the plasma albumin and globulin fractions. In six cases of severe hypoalbuminemia, the albumin deficiency was corrected rapidly. Five hypoproteinemic patients at the terminal stages of their diseases were able to utilize the hydrolysate to maintain a positive nitrogen balance but not to regenerate plasma proteins.

These results are consistent with the belief that diverse medical and surgical conditions are characterized by varying degrees of protein depletion which can be corrected by large amounts of casein hydrolysate.

STUDIES ON THE MINIMUM PROTEIN REQUIREMENTS OF ADULT DOGS

C F WANG, M B CH B, A LAPF, M D AND D M HEGSTED, PH D
BOSTON MASS

THE protein requirements of adult animals including man have been investigated almost exclusively by nitrogen balance studies. This is a reasonable method since only the losses through the skin and those involved in the growth of hair and skin are not taken into account. These are undoubtedly small. However, little work has been directed toward the determination of the proper conditions under which the studies should be made. It is known that when an animal is fed a low protein diet the urinary nitrogen falls rapidly during the first few days and continues to fall for a considerable period, but at a decreasing rate. It seems obvious that the amount of protein required to balance these losses will depend upon the time the studies are made, or the degree of nitrogen depletion of the subject.

The fundamental studies of Terroine and co-workers,^{1, 3} Sorg-Matter,² Ashworth and Budy,⁴ and Smuts⁵ have shown that eventually the nitrogen excretion reaches a minimum which is closely correlated with the basal metabolism of the subject. This minimum may be considered the endogenous level of nitrogen metabolism, and corresponds to 1.4 to 2.0 mg of nitrogen per basal calorie. Since this appears to be minimum nitrogen excretion, it is reasonably certain that the minimum nitrogen requirement cannot be below these levels. For an individual with a basal metabolism of 1,500 calories per day, the minimum daily protein requirement would thus be between 13 and 19 Gm, assuming complete utilization. Most proteins are of course not completely utilized and the minimum requirements are above these levels. The amount above may be calculated from a consideration of the degree of digestibility and the biologic value of the protein fed. The recent studies of Bickei, Mitchell, and Kinsman⁶ and Hegsted, Tsongas, Abbott, and Stare indicate that the protein requirement of human adults is in this range, that is, endogenous requirement plus corrections for digestibility and biologic value, and have yielded minimum values considerably below the previously accepted figures.

However, it must be recognized that although nitrogen balance is an apparently adequate criterion of whether an animal is being maintained with regard to nitrogen, it tells nothing of the condition of the animal thus being maintained. It is not impossible that continued maintenance of an animal in a depleted state may lead to serious consequences. From the studies of Addis and associates^{8, 10} it would appear that animals depleted to endogenous levels of nitrogen excretion would have severely depleted livers, and Elman and co-workers¹¹ have shown that plasma protein levels begin to fall soon after low

chloroform. The chloroform extractable material was dried and weighed. The choline content was determined from another sample after grinding with anhydrous sodium sulfate and extraction with methanol by a modification of the remeckate method.¹⁸

The liver samples for glycogen determination were immediately freed and dropped into a Pyrex tube of known weight containing a known amount of 30 per cent potassium hydroxide. The glycogen content was determined by the method of Good, Kramer and Somogyi.¹⁹

Thin slices (3 to 5 mm.) of all livers were taken at random from any lobe and fixed in formaldehyde formal alcohol picric acid solution of Roman and Zenker wetic fixative sections were prepared by the paraffin or celloidin methods and stained with hematoxylin and eosin or in methylene blue and by the Best carmine method for glycogen. Frozen sections were stained with Sudan IV.

RESULTS

The combined data on nitrogen balance, body weight, nitrogen and calories consumed, blood constituents, and body fluids are presented in Figs. 1 to 6. All dogs received 666 protein at comparable levels for thirty days after the depletion period. At this time the changes in dietary regime indicated in the illustrations and in Table I were made. The results on egg protein will be discussed first.

Nitrogen Balance and Body Weight.—Nitrogen excretion studies were begun after the dogs had received the nitrogen free diet for ten days. At this time the urinary nitrogen was clearly not at minimum levels since, with the exception of Dog 6, all the animals showed a stepwise reduction in nitrogen excretion in

subsequent periods. It is of interest that they showed this drop in nitrogen excretion even though egg protein was added to the diet. This result is in agreement with those of Miller,²⁰ Brush and co-workers,²¹ and Allison and associates.² As has been discussed by these authors, this gives to egg protein a biologic value above 100. It is presumed that the animals would have reached this low level of nitrogen excretion eventually if continued on the nitrogen-free diet. Most of the dogs went into a slight positive balance eventually. Meanwhile the body weight increased slightly. It was the main purpose of the experiment to study the physiologic changes during this period.

Plasma Volume and Plasma Proteins—Prior to depletion, the figures obtained for plasma volume, 41.2 to 60.7 cc per kilogram, total plasma proteins, 6.3 to 8.28 per cent, and total circulating plasma protein, 2.6 to 4.0 Gm per

Fig 1—This figure summarizes the data obtained on Dog 1. TPP % Percentage of total protein in plasma. ALB % percentage of albumin in plasma. HB % per cent hemoglobin. BWT body weight in kilograms. AF/PV ratio of available fluid to plasma volume. NINT nitrogen intake grams per day. NOUT total nitrogen output grams per day. U urinary nitrogen and F fecal nitrogen. PV cc plasma volume in cubic centimeters. TCPP Gm. total circulating plasma protein in grams. T ALB Gm total circulating albumin in grams. T CHB Gm total circulating hemoglobin in grams. AF cc available fluid volume in cubic centimeters. CAL calorie intake per day.

During the ninth week tube feeding (TUB F) was resorted to to maintain nitrogen intake and partial caloric intake.

Fig. 2.—Data obtained on Dog 2. See Fig. 1 for interpretation.

Diagram are normal when compared with those reported in the literature^{1-3,2} During the depletion period all of these decreased somewhat. This is of considerable interest since it indicates that there is a fall in plasma proteins before the minimum nitrogen excretion is reached. When 25 gm. protein was added to the diet all of the dogs with the possible exception of Dog 4 showed a favorable response in total plasma protein. In most dogs this was shown by an increase in plasma volume while the percentage of protein remained essentially constant. In Dogs 4 and 7 the concentration increased somewhat with less marked or no change in plasma volume. The significance of the two types of response is not clear.

During the rest of the periods the level of protein was apparently sufficient to maintain both plasma volume and protein concentration. There is no evidence of a sustained fall indicating further protein depletion. Raising the level of nitrogen intake of Dogs 3 and 7 by 20 per cent may have caused a slight response. Although in Dog 3 the control level of total plasma protein had been reached before the change was made. The last observation on this dog is probably complicated by the failure to maintain a maximum calorie intake. The same is certainly true for Dog 1.

Fig 3—Data obtained on Dog 3 See Fig 1 for interpretation

Hemoglobin—Almost all of the dogs showed some loss of hemoglobin during the depletion period, a total of about 10 Gm per dog. With the exception of Dog 6, which was in relatively strong negative nitrogen balance throughout the study, there is little or no evidence of a progressively developing anemia after egg protein was fed. The percentage concentration of hemoglobin showed marked changes, especially with the changes in diet. The total circulating hemoglobin in spite of the fact that it is a calculated figure, appears to be much more useful in studies of this type in evaluating the nutritional status. The fact that the hemoglobin concentration changes were chiefly the result of the changes in blood volume is apparent from the figures, and the constancy of the total circulating hemoglobin lends considerable support to the correctness, at least relatively, of our figures for plasma volume.

Available Fluid Volume—Unfortunately, available fluid volumes were not determined early in the study, and some of the last values obtained may have been complicated by low calorie intakes. However, after the depletion period and thirty days on the low nitrogen regime the available fluid volume varied from 198 to 237 and the plasma volume from 335 to 554 cc per kilogram of body weight. The ratio of available fluid to plasma volume varied from 38 to

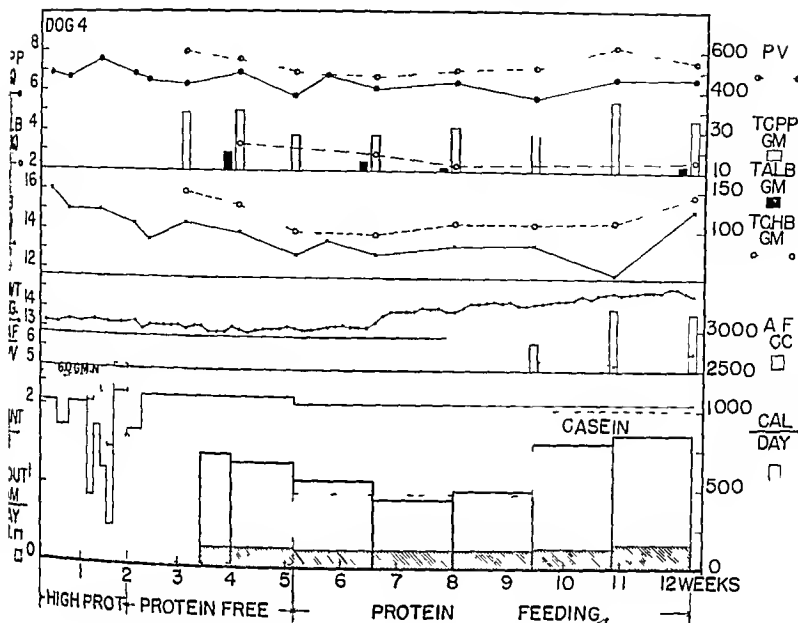

Fig 4—Data obtained on Dog 1. See Fig 1 for interpretation.

68 It is of interest that Dogs 1 and 6 which were in the strongest negative nitrogen balance showed the highest ratios 6.4 to 6.8. The values for the other dogs were in the normal range 3.2 to 3.9. The significance of later values for available fluid is problematical because of the failure of appetite in three dogs. This left only one dog receiving egg protein (at 20 per cent higher level than at the beginning). There appeared to be a steady increase in available fluid volume and ratio although plasma volume was constant. The dog was in slight positive balance after a considerable period of negative balance. Nevertheless this probably represented a continuing tendency toward edema. The opposite trend in Dog 6 was seen when nitrogen balance improved.

Methionine Supplementation—Methionine was added to the diet of two dogs because of reports that this amino acid is effective in conserving body protein.²² Dog 6 responded as expected. The minimum nitrogen fell markedly so that the dog was in balance and this was maintained in the following period even though the level of egg protein was decreased below that used during most of the study. A response in the circulating proteins was accompanied by an increase in plasma volume. Both the total hemoglobin and the hemoglobin content increased. The ratio of available fluid to plasma volume fell. In Dog 2

Fig 5—Data obtained on Dog 6 See Fig 1 for interpretation

the nitrogen balance became more negative. If the changes in plasma proteins and plasma volume are significant, they are opposite to those of Dog 6. The ratio of available fluid to plasma volume was maintained by a slight drop in available fluid. It should be noted that the ratio in Dog 2 was much lower than in Dog 6. There was, however, as in Dog 2, a favorable response in hemoglobin level and total hemoglobin.

It has been reported that the response to methionine is less marked after severe nitrogen depletion.²⁰ The data on nitrogen balance and total circulating protein indicate that Dog 6 was probably the more severely depleted. Thus the better response in Dog 6 was contrary to expectation. However, Dog 2 had previously shown a drop in urinary nitrogen to the endogenous level when given egg protein, while Dog 6 continued in strong negative balance. This may explain the difference in the two dogs at the time methionine was given, but the reason for the failure of Dog 6 to respond previously to egg protein remains unexplained.

Casein Supplementation—Dog 4 was given a relatively high level of casein supplying 2 Gm of nitrogen per day. This was sufficient to throw the dog in strong positive balance. Coincident with this response, all of the values for

Fig 6—Data obtained on Dog 7 See Fig 1 for Interpretation

plasma proteins, plasma volume, hemoglobin and available fluid increased. The ratio AF/PV remained constant between 5 and 6. It may be worth while to call attention to the changes in total circulating protein and plasma volume since this type of response was also observed in some of the dogs when they received protein previously. There appeared to be an increase in total protein as the primary response, and the changes in plasma volume followed this. In the next period the plasma protein apparently redistributed itself to body tissues. The total protein fell somewhat together with the plasma volume but not in proportion since the concentration of protein remained slightly higher than previously.

Liver Analyses—The results for moisture, fat, glycogen and choline are shown in Table I. The results obtained on the five supposedly normal dogs including two which had been given the purified diet containing 30 per cent skim milk powder for thirty days before they were killed are also presented. All animals had livers of normal fat and water content.^{30, 31} The glycogen and choline varied greatly. The loss of protein of liver has been recognized as an early sign of fasting or protein deficiency.^{8, 10} Kosterlitz and Campbell³² found that the losses in protein, phospholipid and nucleic acid during fasting and in protein deficiency represent a loss of liver cytoplasm. They found that

this loss of liver cytoplasm could be expressed by a curve containing an exponential and linear component. The linear decrease is thought to be a measure of endogenous metabolism, while the exponential decrease is probably due to loss of labile liver cytoplasm. These data suggest that the determination of liver nitrogen may be a simple and accurate index in experimental animals of the nutritional status with regard to protein. In Table I the nitrogen content of the livers has been expressed in several ways. If the nitrogen per gram of nonglycogen nontat liver solids is plotted against the average nitrogen intake of the

Fig 7—Diagram showing the relation between the average nitrogen intake milligrams per kilogram of body weight per day during the experimental period and the total liver nitrogen expressed as milligrams of nitrogen per gram of nonglycogen nonlipid liver

dog during the entire study (including the supplements at the end of the experiment), there appears to be practically a straight-line relationship for three of the animals (Fig 7). The two which fall above the line are those which received methionine supplements. These results agree with those recently reported by Brush and co-workers²¹ and indicate a shift of protein toward the liver. It is interesting that this happened in Dog 2 although there was no apparent improvement in nitrogen balance.

The liver nitrogen contents per kilogram of body weight of our dogs are compared with various values taken from the literature in Table II. It is evident that on this basis our animals are considerably below well-fed animals and well above severely depleted animals.

TABLE II. EFFECT OF DIET UPON THE NITROGEN CONTENT OF DOG LIVERS

SOURCE	DOG NO	DIETARY CONDITIONS	AVERAGE LIVER NITROGEN (GM /KG BODY WEIGHT)
Grund ²⁴	6	133.366 Gm N per kg body weight per day for 20 or 35 days	1.06
	4	Fasting for 13-19 days	0.57
Pughese ³	2	Normal	0.91
	2	Fasting for 20-24 days	0.60
	2	250-300 c.c. of milk given daily for 4 days after 28-30 days' fast	0.81
Authors	4	2 mg N per basal calorie from egg protein for 40 or 50 days following 2-3 weeks on nitrogen free diet	0.72
	2	Same as Dog 4, plus methionine for 10 days	0.75
	2	Normal, high protein diet for 30-40 days	1.15
	3	Normal dog chow and hormone	0.89

Pathology —

Gross Except for a dark blue green color imparted by the Evans blue dye to the liver, no striking changes were noted. All livers were smooth and the capsules glistened. The borders were sharp. Although all of the livers were firm, there was no increase in resistance to section. The weights of all livers are recorded and compared with body weight in Table I. The other organs showed no significant changes. The livers of the five normal dogs also showed no significant change.

Microscopic The changes found in the livers of experimental animals 2, 3, 4, 6, and 7 differed only quantitatively, in that all were similar to those described by Ulman and Heifetz³⁰ in dogs on protein deficient diets.

There was marked swelling of liver cells and cell membrane was well defined and intensely stained. So extensive was the swelling of liver cells that the sinusoids were largely obliterated. Most striking of all changes was the marked rarefaction of cytoplasm which was represented by a few eosinophilic granules of the cytoplasm identified as ribonucleic acid by various techniques (see review by Greenstem³⁶).

The liver cell nuclei were uniformly small, central and round or oval with a scant amount of fine, evenly dispersed chromatin material and prominent, often multiple nucleoli. In many instances binucleated cells were seen and in one animal (Dog 4) many of the nuclei were hyperchromatic.

In most livers, the Kupffer cells were unusually prominent because of coarse dark chromatin granules in their nuclei and fine brown pigment granules in the cytoplasm.

The changes in liver cells described affected the entire parenchyma but were most severe in the portal areas. In some of the central areas there was more intense staining and a few identifiable sinusoids indicating less rarefaction of cytoplasm and less swelling of the cells.

The livers of all experimental animals stained intensely for glycogen and were not distinguishable, one from another on this basis. The liver of only one of the control dogs fed on a high protein diet showed any appreciable amount of

glycogen by histochemical examination and even in this instance the amount was estimated to be less than half that found in the experimental animals. It appeared to be equally distributed between the portal and central areas, with considerably less present in the mid-zonal region. In the five normal dogs examined, only occasional patchy areas of glycogen were encountered. The three of these dogs which received chow and meat had been fasted sixteen to twenty hours, but the two receiving the high protein diet were killed at the same interval after feeding as the experimental animals. The significance of this apparent increase in liver glycogen in protein-depleted dogs is unknown.

Although stainable fat was present in appreciable quantities in the cytoplasm of the cells of the bile duct epithelium in the livers of all experimental animals, and to a lesser extent in the control and stock animals, none was found in the liver parenchyma of any animal. It may be concluded that the choline provided in the diet and the methionine fed as such or as protein was sufficient to prevent the development of fatty livers. The morphologic changes described as occurring in the livers of the experimental Dogs 2, 3, 4, 6, and 7 are probably wholly the result of protein deficiency. The accumulation of fat in the livers of protein deficient dogs described by Elman & Herfitz³⁰ may be due in part to choline deficiency.

Appetite—Of the six dogs started in this study, three showed marked failure of appetite toward the end of the study. This undoubtedly has had some effect upon the analytic values obtained, although it is not evident what this effect may be. There is also no certainty that the failure of appetite is specifically due to protein deficiency, although we consider this a likely possibility. The nitrogen intake of the dogs was maintained by tube feeding during this period, but it was impossible to maintain the caloric intake.

DISCUSSION

We have attempted to evaluate the adequacy of a protein level thought to be near a theoretical minimum, which would correspond to about 20 Gm in an average human adult. Numerous questions still remain unanswered and the study is being continued, but the present results are instructive. For the reasons discussed in the introduction, the animals were partially depleted of protein prior to being given the low level of protein. During this depletion period the data show that from 96 to 230 Gm of body protein were lost. This was accompanied by a loss of 9.5 to 13.5 Gm of circulating plasma protein. The percentage of plasma protein was also decreased slightly, but, without prior knowledge of the plasma levels, would be considered to be in the normal range. *These changes occurred before a minimum level of urinary nitrogen excretion was reached.* In our opinion the data on urinary nitrogen excretion and plasma proteins alone would not be considered indicative of severe protein depletion.

During the next four to six weeks when egg protein was fed, all of the analytic data indicate that the animals were maintained in this condition. The general average indicates that nitrogen balance was achieved, and the other constituents measured show no consistent deterioration. The changes during

the period on egg protein are summarized in Table III. However, we interpret the microscopic findings, swelling of the liver cells with marked rarefaction of the cytoplasm as indicating relatively severe liver depletion. Since the animals appeared to have been maintained, this degree of depletion was probably achieved during the period on the nitrogen free diet rather than while the egg protein was being fed. It is impossible to state how severe this depletion was or how serious the consequences were for the animal but the livers of these animals could not be considered normal. Thus we conclude that the animals which had not been depleted to an endogenous or minimum level of nitrogen excretion were nevertheless too severely depleted to be considered normal and that this base line is too severe to be used for studies which are to be interpreted in terms of normal animals. It seems further apparent that a barely detectable loss of plasma protein has reflected relatively severe liver depletion and that plasma protein determinations are insufficiently sensitive to evaluate such changes.

A, End of depletion B thirty days on egg protein

The figures in parentheses are estimated from determinations obtained a few days before and after the desired date

The fact that appetite failed in most of these animals is a serious consequence. One cannot rule out possible deficiencies of other dietary factors as the causes of this, but dogs have been maintained upon a similar diet containing purified casein for long periods. It is not impossible that the low protein diets may change an animal's requirement for other nutrients but until this is shown we feel we must consider the loss of appetite as a symptom of protein deficiency. This has been observed in other studies on dogs to such an extent as to preclude

completion of the work.³⁷ Frazier and co-workers³⁸ have emphasized the immediate effect on appetite of acute amino acid deficiencies. It has been suggested that this is a protective mechanism and that the other amino acids may actually be detrimental in the absence of an essential one. It is also possible that caloric intake itself may be detrimental in this sense since this undoubtedly necessitates considerable work on the part of the liver. However, we have the impression from work during the past several years on low protein diets that the dog and rat are hardly comparable with regard to appetite. Although the food intake of protein-deficient rats is reduced, we have seldom seen a complete failure of appetite such as frequently occurs in dogs, and with rats this usually only has been seen with very severely depleted animals. In dogs, on the other hand, this may be the first suggestion that the diet is unfavorable. In this respect the dog is probably more nearly like human beings. Regardless of whether or not the reduction of food intake is considered a protective mechanism, the vicious cycle of mild deficiency \rightarrow loss of appetite \rightarrow severe deficiency is indeed vicious if it reaches the stage where the animal fails to eat an adequate diet when offered.

The differences in the response of the plasma proteins to the feeding of protein were interesting. If the time intervals between determinations had been shorter, it seems likely that the responses might have been more uniform. In most of the animals the response was in plasma volume rather than in the percent of plasma protein. When plasma protein was increased, this generally appeared to be redistributed to other tissues. Thus the priority seems to be for the maintenance of blood volume and for other tissues rather than for an increase in the concentration of the plasma proteins. If one could determine that level of protein intake at which the plasma levels begin to rise, indicating adequate plasma volumes and flow of protein to less essential systems, this might be a true minimum requirement. However, as mentioned earlier, it is not likely that the determination of plasma proteins would be sufficiently sensitive to identify this point with any assurance.

In a previous discussion,³⁹ one of us has pointed out that the effect of methionine or egg protein supplementation in lowering the excretion of urinary nitrogen appears to be a lowering of urinary nitrogen to endogenous levels without serious nitrogen depletion. Although it is not clear how this is brought about, it is interpretable if on a nitrogen-free diet the chief deficiency is of methionine. The animal appears to break down proteins and waste other amino acids in order to obtain sufficient methionine. This is consistent with the fact that methionine has functions other than protein synthesis.

It is our conclusion from the present work that the common practice of depleting animals to low nitrogen excretion levels prior to studies on nitrogen requirements is not justified. Levels of nitrogen which apparently maintain such animals in nitrogen balance and also maintain plasma proteins and weight within the low normal range may not be adequate, as evidenced by liver pathology and failure of appetite. However, this level of nitrogen may still be adequate to maintain an animal which has not been depleted, especially if methionine is supplied. Studies similar to these but without prior depletion are needed for the answer to this problem.

SUMMARY

In determining nitrogen requirements, it is recognized that some nitrogen depletion is necessary if minimum requirements are to be determined. Various investigators have considered it desirable to deplete animals to a minimum nitrogen excretion if minimum nitrogen requirements are to be determined. In this study 2 mg of nitrogen (as egg protein) per basal calorie were fed to dogs which were only partially depleted as evidenced by urinary nitrogen levels. Nitrogen balance, plasma protein, plasma albumin and hemoglobin concentrations, plasma volume, thioeyanate space, total circulating plasma protein, total circulating hemoglobin, body weight, liver analyses and microscopic examination at autopsy were used to evaluate the adequacy of the level of protein fed.

A slight fall in plasma protein and hemoglobin (both as per cent and as total circulating) was observed before minimum nitrogen excretion was reached. After this partial depletion all of the criteria except the last two in the foregoing list indicated that the animals were being maintained in this condition by the level of protein fed. Chemical analyses of the liver indicated considerable but not excessive nitrogen depletion. However, the microscopic examination of the livers revealed swelling of the liver cells, marked rarefaction of the cytoplasm, and loss of basophilic granules (ribonucleic acid). These changes are considered indicative of severe nitrogen depletion. Appetite also failed in most of the animals.

It is therefore concluded that (1) this level of nitrogen could maintain partially depleted animals insofar as the usual tests for nitrogen metabolism (nitrogen balance, plasma protein concentration) are concerned (2) the animals were too severely depleted to be considered normal as evidenced by the pathologic changes in the liver and the failure of appetite (3) the chemical and physiologic tests used are either inappropriate or insufficiently sensitive to determine the degree of nitrogen depletion indicated by liver examination and (4) further work using nondepleted animals is required to determine if dietary nitrogen fed at the endogenous level of nitrogen excretion will maintain normal animals.

A METHOD FOR THE DETERMINATION OF PLASMA CATALASE AND THE VALUES OBTAINED IN NORMAL ADULTS

ROGER S DILLE, M D,* AND CHARLES H WATKINS, M D †
ROCHESTER, MINN

LOEW,¹ in 1901, demonstrated that there was a characteristic enzyme in all plant and animal cells with the specific action of decomposing hydrogen peroxide into water and oxygen which he named "catalase." In mammals, the erythrocytes liver and renal cells contain relatively much more catalase than do other tissues. The clinical importance of the catalase activity of whole blood has been shown to be little or none and the changes in health and disease have been shown to parallel the erythrocyte counts, although in general there has seemed to be less of this enzyme in the red cells in the various anemic states.

The catalase content of plasma or serum in human beings has received scant study. Becht² using relatively crude methods, found evidence of slight catalase activity in serum, as did Jolles and Oppenheim.³ Oppenheimer⁴ stated that the low values found in serum probably were the result of red cell destruction but he did not make clear whether he meant *in vitro* or *in vivo* lysis. Perlmann and Lipmann⁵ showed that catalase is found in the various fractions when the proteins of serum or plasma are fractionated.

Description of a clinical method for the determination of catalase activity in serum or plasma has not been found in the literature. Kurokawa⁶ presented observations on dog plasma based upon the original method of Jolles. He stated that, in the dog, bleeding had little effect on the plasma catalase activity, but that injection of distilled water, direct hepatic trauma, and hepatic poisons gave increased values.

We have developed, for the determination of catalase in plasma, a relatively simple clinical method which yields results that are reproducible within 5 per cent, most determinations checking within 2 per cent. This method is similar to that of Jolles in principle but it has been modified to increase the sensitivity for the small amounts of catalase which are found in plasma. The procedure is based upon the determination of the amount of hydrogen peroxide decomposed in a given time by a specific dilution of plasma under constant conditions. When a 1:50 dilution of plasma, in a solution containing 0.02N hydrogen peroxide and 0.8 per cent sodium chloride at a pH of 6.8 (0.006M phosphate buffer), is incubated at a temperature of 22 to 23° C. for twenty minutes, the decomposition of the peroxide in each cubic centimeter of the mixture is designated 1 unit of catalase activity. Hydrogen peroxide is measured by the determination of the amount of iodine liberated from iodide (catalyzed by molybdate), conventional thiosulfate titration being used.

Received for publication Nov. 25, 1947.

MATERIALS AND SOLUTIONS

1 Powdered heparin The product of the Connaught Laboratory which contains 110 cat units per milligram is used This should be finely powdered and tested for catalase activity We have found no indications of the presence of catalase in the several lots used

2 Concentrated phosphate buffer and saline A 0.08M phosphate buffer at a pH of 6.8 is prepared and enough sodium chloride added to make an 8 per cent saline mixture This is sterilized by boiling and kept under sterile conditions to prevent mold growth which may have catalase activity

3 Superoxol

4 A 0.01N hydrogen peroxide buffer and saline solution This is made by adding about 0.6 cc of superoxol to 50 cc of the concentrated buffer saline mixture and diluting to 500 cubic centimeters Ten cubic centimeters of the resulting mixture should require from 0 to 2 cc of 0.01N thiosulfate This solution is made fresh daily and is used within four hours of preparation

5 A 0.01N thiosulfate solution This is made by diluting a 0.1N stock solution of sodium thiosulfate

6 A 10 per cent solution of potassium iodide

7 A 1 per cent solution of ammonium molybdate

8 A 5 per cent by volume sulfuric acid solution

9 A 1 per cent solution of starch

PROCEDURE

As much finely powdered heparin as can be obtained on the tip of a tooth pick is dusted into a 20 cc syringe A like amount of heparin is dusted into a 15 cc centrifuge tube which has a paraffin covered cork With a 19 gauge needle about 17 cc of blood are slowly withdrawn from an arm vein in the usual manner care being taken that bubbles of air are not sucked through the blood The needle is removed from the syringe and the blood is allowed to flow gently down the slanting side of the centrifuge tube until the tube is almost full The cork is inserted and the tube is gently inverted once The blood is then centrifuged at a moderate speed for fifteen minutes About half of the plasma is carefully removed and recentrifuged for a like period Then 0.2 cc of plasma in a Kahn pipette is added to 10 cc of the hydrogen peroxide buffer mixture and the solution is surged back and forth in the pipette to insure complete removal of all of the plasma A 120 cc Erlenmeyer flask should be used for this mixture The solution should be at a room temperature of 22 to 24° C if the temperature is above or below this a water bath kept at this temperature must be employed Twenty minutes later the enzymatic action is stopped by adding 10 cc of sulfuric acid solution A blank is run in an identical manner except that the sulfuric acid solution is added to the peroxide before the plasma is added Five cubic centimeters of the 10 per cent iodide solution and 1 drop of the solution of ammonium molybdate are added to each flask After three minutes the liberated iodine is titrated with the thiosulfate solution in the usual manner The volume, in cubic centimeters, of 0.01N thiosulfate solution of the blank minus that required by the plasma assay, multiplied by 2.5 gives the catalase activity of 1 cc of plasma in terms of the units previously defined If duplicates do not agree within 5 per cent, the test is repeated

Comment—It was found that the drawing of bubbles of air through the blood during withdrawal gives high values owing to destruction of erythrocytes

Fig 1—The effectiveness of hydroxylamine in inhibiting the catalase activity of lysed erythrocytes and plasma

For the same reason it is necessary to allow the blood to flow gently into the centrifuge tube and to avoid squinting. By comparison, it was found that heparin-treated plasma gives lower catalase values than does plasma prepared by the various citrate or oxalate methods. Serum also was found to give much higher values owing to cell destruction during coagulation. Cell-free plasma was found to lose its catalase activity upon standing, in one hour about 10 per cent loss occurs.

That the decomposition of hydrogen peroxide in the procedure just described is due to catalase in the plasma and not to the oxidation, by the peroxide, of the

Fig 2—The effect of temperature changes on the catalase activity of plasma

many oxidizable substances known to exist in plasma was shown by various methods. Urine diluted 1:50, with enough glucose added to make a concentration comparable to that of plasma, gives no decomposition of peroxide under the conditions of the present method. It is well known that hydroxylamine is an inhibitor of the action of catalase. As shown in Fig 1 the presence of hydroxylamine completely inhibited the decomposition of hydrogen peroxide by plasma or by lysed erythrocytes.

Another proof that catalase activity is responsible for the observed action is the reduction of the maximal amount of decomposition of peroxide with temperature increases. When time and the amount of peroxide conversion are plotted at various temperatures, curves are obtained as in Fig 2. If non-enzymatic oxidation reactions were involved one would expect increased activity at higher temperatures, a plateau being reached only when all peroxide was consumed or all oxidizable substances were oxidized. It will be noted that at 45°C a plateau is quickly reached but the curves at lower temperatures indicate that this could not be due to lack of available peroxide or oxidizable substances. Likewise, the curve at 22°C shows a maximum of activity which is lower than the maximum reached at 0°C. The curves are explained by the known peculiarities of catalase. Unlike most enzymes catalase is rather rapidly inactivated by its substrate. This inactivation is at a minimum at freezing but rapidly increases with relatively small increments in temperature.

The question arises as to whether peroxidase activity may not complicate the estimation of catalase activity. This complication is unimportant, according to the following calculation. If one uses the liberal value for phenols, including tyrosine, epinephrine and bilirubin, in the blood plasma of 10 mg per 100 cc and, using the molecular weight of tyrosine, assumes that one mole of oxygen is used per mole of substrate, it can be calculated that not more than 0.008 mg of oxygen would be consumed per cubic centimeter of plasma, whereas the oxygen liberated from the hydrogen peroxide by 1 cc of plasma, the mean value for the method being used, amounts to 1.12 mg, hence, less than 1 per cent of the observed value could be ascribed to peroxidase action.

Several other factors indicate that peroxidase activity does not occur under the conditions of the test. No darkening of the reaction mixture, which one might expect if there had been any appreciable oxidation of phenolic compounds, was observed during the test. When plasmas containing much bilirubin—so much that the reaction mixture was a faint yellow—were tested, there was observed no change to the green tint during the enzymatic period which would have been expected if peroxidase activity had been present. It may be remarked that the bilirubin in these instances was oxidized to biliverdin, which gave a green tint, due to oxidation by the free iodine liberated during the assay of the hydrogen peroxide.

It would be difficult to prove that the catalase activity observed was not due to the destruction of erythrocytes during the collection and preparation of the plasma. It can be stated that the method presented gives the lowest values for catalase activity when compared with other methods of preparation of plasma or serum. As will be shown later in another paper on hemolytic diseases, in conditions in which an increase in plasma catalase would be expected, the values for catalase activity are actually much higher than the normal upper limit but, after correction of the hemolyzing process, the values become more nearly normal. That heparin itself is without effect on the erythrocytes is indicated by the fact that a specimen of blood containing heparin in the amounts specified in this method and another containing about ten times this amount yielded the same results in duplicate.

The use of paraffin-lined tubes and oiled syringe gave, in some instances, higher values when compared with heparin duplicates, in other cases closely checking results were found, but in no instance was a value lower than that of the heparin duplicate observed. The possible disruption of erythrocytes during centrifugation was minimized by the use of moderate speeds and by avoidance of rapid increases to top speeds.

A second problem presented itself, namely, whether the catalase activity of the erythrocytes influences the activity as observed in the plasma. This was investigated by making a 1:500 dilution of the erythrocyte layer after centrifuging, a 0.2 per cent solution of sodium carbonate being used as diluent. Then 0.2 cc of this lysed erythrocyte solution was assayed for catalase activity by use of the same method as for plasma except that a thirty-minute digestion period was used. The hemoglobin of the solution was determined by means of

a Photometer. The amount of hemoglobin expressed in grams per 100 cc of erythrocyte layer and divided by the catalase activity of 1 cc of the 1:500 solution of lysed erythrocytes was designated the hemoglobin catalase coefficient.

RESULTS

The plasma of fifty adults was assayed for catalase activity by the method described. These people were all classed as normal inasmuch as the value for hemoglobin was more than 13.0 Gm per 100 cc of whole blood and they were considered free of serious disease or disorders in which one would anticipate tissue or blood destruction.

Fig 3—Distribution of catalase activity of the plasma in fifty one normal adults

Normal values were found to range from 42 to 95 catalase units per cubic centimeter of plasma, the mean was 69 catalase units. When these values were smoothed to the nearest whole or half number a distribution curve was obtained as shown in Fig 3.

The hemoglobin catalase coefficient varied from 2.4 to 3.3 in the twenty five cases in which it was determined. No correlation was found between this coefficient and the catalase activity of the corresponding plasma, showing that the catalase activity of erythrocytes does not influence the plasma activity.

The daily values for plasma catalase activity in a normal adult over a period of five days were 95, 85, 95, 70, and 95, respectively. Although but little fluctuation was found in this instance more determinations on various people are needed before definite conclusions can be drawn.

SUMMARY

A method for the determination of catalase activity of human plasma has been presented. The normal values obtained in fifty adults were found to range from 4.2 to 9.5 catalase units per cubic centimeter of plasma, the mean being 6.9 catalase units. No correlation was apparent between the catalase activity of the erythrocytes and the catalase activity of the corresponding plasma.

PLASMA CATALASE IN HEMOLYTIC DISEASES AND OTHER ABNORMAL STATES

ROGER S. DILLE, M.D.* and CHARLES H. WATKINS, M.D.†
ROCHESTER, MINN.

A PREVIOUS report¹ has described a clinical method for the determination of plasma catalase and has established normal values for adults. By the use of this method abnormal states have been studied. The procedure has been varied slightly in that with the higher catalase values reached in disease states (with values greater than 50 units, which is the limiting value in the method as described) smaller dilutions of plasma were necessary. Usually 0.2 cc. of plasma in 50 cc. of the hydrogen peroxide and buffer mixture was used when there was reason to expect very high catalase values or when values of more than 50 were found using the regular procedure. The catalase coefficient of the erythrocyte layer was determined as described in the preceding paper.

Because erythrocytes, liver cells and renal parenchyma are relatively rich in catalase, one might theoretically predict some of the known clinical conditions in which an increase in plasma catalase could be found. Any condition in which destruction of erythrocytes was occurring to a greater degree than normally occurs in the blood stream would be expected to give a rise of concentration of catalase in the plasma. Those states in which this might be anticipated include transfusion reactions, congenital and acquired hemolytic anemia, pernicious anemia in severe relapse, acute infections causing rapid anemia, paroxysmal hemoglobinuria, nocturnal hemoglobinuria and the condition produced by injection of distilled water or other hypotonic solutions. Certain other conditions in which excessive destruction of blood is occurring with release of the contents of the erythrocytes into the blood stream include phlebotrombosis, infarctions of all types (especially myocardial infarctions with formation of large mural thrombi), hemorrhage into the thoracic or peritoneal cavities and crushing injuries.

Conditions in which there is rapid destruction of hepatic parenchyma such as acute yellow atrophy, acute hepatitis (infectious), poisoning from the various hepatic toxins, and crushing injury to the liver would be expected to show some increase in plasma catalase.

There are few renal diseases in which rapid destruction of parenchyma usually occurs but it is possible that poisoning by the heavy metals might show some change in plasma catalase activity.

We have investigated the plasma catalase in some of the disease states mentioned. Kurokawa² had found that in dogs injections of distilled water, trauma to the liver, and hepatic poisons gave increases in plasma catalase. We were

$\frac{\text{Hb}}{\text{C A}} = \frac{\text{Hemoglobin of erythrocyte layer (Gm per 100 c c)}}{\text{Catalase activity of erythrocyte layer per cubic centimeter of 1:500 dilution}}$

The results in patients with hemolytic anemia not operated on or who had undergone splenectomy are presented in Table II. It will be noted that the patients with severe acquired anemia had very high catalase values. The patients with congenital anemias who had undergone splenectomy had normal values. The remaining two patients with congenital hemolytic anemia who were not operated on at this time had only mild anemia with relatively low reticulocyte counts. The plasma catalase activity of systemic venous plasma was a little greater than normal in one case and normal in another, thus also was noted in two of the patients with hemolytic anemia in Table I who underwent operation. One can probably assume that because in these cases the spleen is the organ of destruction and the liver removes catalase from the blood plasma normal or near normal values would be found in the congenital types of hemolytic anemia except during marked exacerbations or crises whereas in the acquired types of hemolytic anemia in which the site of blood destruction is more general possibly in the blood stream itself higher values will be found.

Again the catalase coefficients of the erythrocyte layer were essentially normal indicating no great change in the catalase content of the erythrocytes as compared with normal amounts.

Table III presents the catalase and other pertinent values obtained before and during the treatment of pernicious anemia. That an excessive destruction of erythrocytes occurs in severe pernicious anemia is well known not only by the increased indirect serum bilirubin value but also by the increased urobilinogen output in the feces. In the days before liver therapy, the finding of excessive hemosiderin at necropsy in cases of pernicious anemia was often noted.

As shown in Table III all the patients who had pernicious anemia except one showed rather marked increases in the plasma catalase activity. It is also apparent that a prompt fall to normal values occurred coincidentally with the

reticulocyte response In one case (Case 22) in which the reticulocyte response was not marked, the values fluctuated consistently above normal Fig 1 also illustrates the responses obtained in a typical case

The most plausible explanation for the excessive destruction of erythrocytes in pernicious anemia has been that the poikilocytic and anisocytic cells, which are so numerous, withstand the trauma of circulation more poorly than normal cells The administration of liver seems to correct the production of these abnormally weak cells immediately, those already present are soon destroyed and the normal rate of destruction of erythrocytes with normal plasma catalase values is quickly established, as is indicated by the cases presented Although this has been shown previously, using serum bilirubin values during treatment as an index of destruction of erythrocytes, the use of plasma catalase values gives a more direct proof of these rapid changes during liver therapy

Fig 1—The effect of liver therapy on the plasma catalase hemoglobin and reticulocytes in pernicious anemia

The catalase coefficients are essentially normal and the changes during treatment do not vary enough to justify considering changes in the catalase content of the erythrocytes during treatment as a determining factor

The values for plasma catalase found in cases of anemia secondary to renal disease are given in Table IV The high catalase activity found in many of these cases was an unanticipated finding with no immediate explanation The bilirubin in these cases was not elevated nor has any previous evidence been found indicating that an excessive rate of destruction of erythrocytes was occurring in such cases of anemia Some patients were not anemic and none of

them were severely anemic. Because all of them were anemic it was possible that the abnormal amounts of metabolic end products in the plasma were being directly oxidized by the hydrogen peroxide, *but by using hydroxylamine it was shown that these values were due to catalase alone.* It is known that renal parenchymal cells are rich in catalase, but one can hardly explain these values by excessive destruction of renal tissue in the light of present knowledge of chronic renal disease. There was no correlation between the catalase activity in these cases and the blood urea, blood creatinine, or the inorganic constituents of the plasma.

 C.A. = Catalase activity of erythrocyte layer per cubic centimeter of 1:500 dilution
 *Diffuse arterial disease

Again the catalase coefficients of the erythrocyte layer are within normal limits, a fact which shows that changes in catalase of erythrocytes were not a deciding factor.

It has been shown previously that hemolysis of blood occurs during prostatectomy.³ This is probably due to the forcing of the distilled water which

is used to irrigate during the procedure into the venous openings in the prostatic beds. It was considered that the use of our method before and after prostatectomy would be of interest. Table V presents the results obtained. As indicated, in all but one case appreciable, and in many cases marked, increases of plasma catalase were found after prostatectomy. In several cases the plasma was grossly

hemolytic. We consider these results an additional check on the validity of the method previously presented.¹ We also noted that these increased amounts of plasma catalase were not as rapidly removed as one would expect. Further studies comparing plasma catalase with plasma hemoglobin after prostatectomy would be of interest. We think that this method will be more sensitive than the present plasma hemoglobin procedures for detecting minimal hemolysis.

Hb = Hemoglobin of erythrocyte layer (Gm per 100 cc)
 C.A. = Catalase activity of erythrocyte layer per cubic centimeter of 1:1000 dilution

Table VI gives values obtained in some miscellaneous cases. It is of interest that the presence of jaundice per se does not influence the values obtained. There is some indication that the high value found in Case 59 was due to increased destruction of erythrocytes (blood film and indirect bilirubin). Case 61 was of unusual interest. The patient had no splenomegaly or familial history. She presented a story of an attack of jaundice a year previously following sulfonamide therapy which was then considered to be responsible. The blood film increased indirect bilirubin, and increased catalase values would indicate that excessive destruction of erythrocytes was occurring. That in two cases of polycythemia the concentration of plasma catalase was greater than normal is of interest in that on theoretic grounds some increase would be expected. The catalase coefficient of the erythrocytes in the few cases in which this procedure was done again was within normal limits.

Because of the similarity of the chemical structure of catalase and hemo-
globin, it is of additional significance that their ratio does not vary from normal
in the various disease states studied

SUMMARY

A discussion of various disease states in which increased plasma catalase
might theoretically be expected has been presented

Using a method previously described,¹ plasma catalase values have been
determined in a number of disease states in which elevated levels might be ex-
pected. Elevated levels were found in acquired hemolytic anemias and in some
familial hemolytic anemias. Differences in plasma catalase of splenic arterial
blood and venous blood were found. Increased plasma catalase values were
present in pernicious anemias and rapidly fell to normal with treatment. In-
creased amounts of catalase were present in the plasma in some cases of chronic
renal disease. Moderate to marked plasma catalase activity was found after
prostatectomy in which distilled water was used as the irrigating medium.
Sundry other diseases in which excessive plasma catalase would not be expected
gave normal values. The determination of plasma catalase may be of practical
value in diagnostic problems.

The ratio of hemoglobin to catalase did not vary from normal in the disease
states studied. Thus, variation in the catalase of erythrocytes was not a de-
termining factor in the changes from normal found in plasma catalase in the
cases presented.

EFFECT OF VARIOUS LETHAL PROCEDURES AND THERMAL INJURY ON CAPILLARIES

MYRON PRINZMETAL, M D, H E KRUGER AND H C BERGMAN, PH D
LOS ANGELES, CALIF

THE role of capillary hyperemia in shock has long been a subject of controversy but in the past, errors of interpretation have arisen in part because of inadequate methods of tissue examination^{1, 2} One potential source of error was uncovered when it was shown that congestion was often masked in unexsanguinated specimens³ If an animal dies from shock and sufficient time is permitted before the organs are removed it is found that the organs of the shocked animals appear similar to or only slightly more congested than the corresponding organs of nonshocked animals On the other hand if the animals are killed by exsanguination the organs of shocked animals are much more congested than the organs of the unshocked animals Similarly when organs are removed in vivo, the difference in the amount of congestion in the shocked and unshocked animals becomes manifest only after the extirpated organs are permitted to bleed out

There is a second potential source of error which may invalidate many previous studies on congestion in shock The agent used to kill the experimental animal may in itself be responsible for a considerable amount of congestion In this instance fallacious conclusions would be drawn if the organs of an animal dead of shock were compared with the organs of a nonshocked animal destroyed by a lethal dose of anesthetic⁴

The method employed in this laboratory for estimating the degree of congestion is a comparison of the amount of hemoglobin and the number of capillaries in the exsanguinated organs of shocked and nonshocked animals The procedures for making hemoglobin assays⁵ and capillary counts with the use of special stains for the erythrocytes⁶ have been previously described

If these possible sources of error are taken into account it becomes evident why a pathologist who examines the tissues in the usual way is unable to determine with precision the amount of congestion in a given organ at autopsy In the first place he has no opportunity to estimate the amount of congestion by comparing exsanguinated organs Second he does not make hemoglobin assays and capillary counts Third, there is a possibility that terminal capillary atony occurs in death from a variety of causes other than shock

It is the latter possibility that requires further investigation, and to this end experiments were performed with a variety of lethal agents to determine to what extent they are capable of producing capillary hyperemia

Experiment—The object of the following experiment was to ascertain the amount of congestion which develops in a test visceral organ the kidney

Received for publication Jan 16 1948.

after a number of designated lethal procedures. A separate group of animals was subjected to fatal thermal trauma in order to compare the amount of congestion in a classic form of shock with that in the first group.

Forty-two Long-Evans rats weighing from 153 to 374 grams were divided into seven groups of six animals each and treated in the following manner. Under local anesthesia, with procaine, the right renal pedicle of each animal was tied and the kidney removed and allowed to bleed freely. The animals were then killed by various means. In the first five groups, death was produced by sodium pentobarbital (0.4 cc intravenously), procaine (0.4 cc intravenously), sodium cyanide (8 mg intravenously), ether (by inhalation), and asphyxia (by clamping the trachea), respectively. In the sixth group, death was caused by a severe burn (immersion to the thorax at 100° C for thirty seconds). In the seventh group, death was produced by rapid exsanguination from the abdominal aorta.

Fig 1—Relative amounts of hemoglobin retained in the exsanguinated kidneys of rats subjected to various lethal procedures. The control kidney was removed first under local anesthesia. After death the second kidney was removed and the hemoglobin content compared with the control. The pooled kidneys of six animals were used in each test.

The latter group served as a further control. Twenty minutes after death, in each instance the second kidney was removed and allowed to bleed out. The hemoglobin content of both kidneys of each animal was then ascertained.

Results—In every instance the second kidney contained a significantly greater amount of hemoglobin than the kidney removed before the animal was killed. In the seventh group, in which death was by exsanguination only, the increase was a small one. The findings are presented in Fig 1 in terms of the ratio of hemoglobin in the kidney removed after death to that in the control kidney.

This experiment shows that various lethal procedures as well as burns cause congestion in a test visceral organ and that the amount of congestion is quantitatively of the same order as that which develops in fatal burn shock.

Fig. 2—Comparison of kidneys before and after a fatal burn. One kidney (A) was removed immediately before scalding of the body up to the head at 100° C for two minutes and is the control for the second kidney (B) which was removed three minutes after the burn. Both kidneys were exsanguinated after removal. Note the dark engorged appearance of the second kidney with little blood around it and the pool of blood around the pedicle of the first kidney after exsanguination.

Fig. 3—Comparison of kidneys before and after a lethal dose of ether. One kidney (A) was removed immediately before administering ether and is the control for the second kidney (B) which was removed after fatal etherization. Both kidneys were allowed to self exsanguinate. Note the dark engorged appearance of the second kidney and the pool of blood around the pedicle of the first kidney.

This experiment confirms previous observations that the degree of congestion can best be demonstrated by making comparative examinations on exsanguinated organs.

In order to illustrate pictorially the effect upon the kidneys of a severe burn and a lethal dose of ether, respectively the following experiments were performed. Two animals were used. In each instance one kidney was removed

under light ether anesthesia and allowed to bleed out. The first animal was killed with ether, and the second by a severe burn. The second kidney of each animal was then removed and allowed to bleed out. Kodachromes were taken of the two sets of kidneys (Figs 2 and 3). The engorgement of the second kidney in each instance is striking.

DISCUSSION

If an animal dies from shock and sufficient time is permitted before the organs are removed, it is found that the organs of the shocked animal appear similar to, or only slightly more congested than, the organs of a nonshocked animal. In previous communications it was shown that the difference between the gross appearance of the organs of shocked and nonshocked animals becomes manifest if the animals are killed by exsanguination.³ Obviously when tissues are taken for study some time after death has occurred, it is no longer possible to make such a comparison. The importance of exsanguination before examining the tissues in shock may explain previous failures to appreciate fully the vascular factor in shock.

In the present report it was shown that asphyxia, lethal doses of pentobarbital, procaine, sodium cyanide, and ether cause visceral congestion. In each instance the hemoglobin content of the kidney removed just prior to the administration of the fatal dose and allowed to bleed out was compared with that of the second kidney removed and treated similarly twenty minutes after death. When the two kidneys were similarly compared in the instance of death from exsanguination, it was found that the hemoglobin content of the second kidney was greater than the first, but that the amount of increase was much smaller than in the other experiments. The operative procedure involved in the removal of the first kidney causes a certain amount of trauma, and this could explain why in the exsanguination experiment the second kidney contained more blood than the first. In the experiments with the other lethal procedures, the difference in the hemoglobin content of the two kidneys was striking. Over seven times as much blood was found in the kidneys of the animals killed with cyanide.

These observations clearly show that capillary atony leading to visceral congestion develops from a wide variety of causes. The list includes burns, asphyxia, lethal doses of various drugs, and muscle crushing injury⁶; it is highly probable that death from many other causes is accompanied by capillary congestion. In determining whether visceral congestion is present in fatal shock, it would be a mistake to compare the degree of congestion in organs of animals in shock with that in corresponding organs of control animals sacrificed by a lethal dose of a substance like pentobarbital or ether. The utilization of these agents for the sacrifice of control, nonshocked animals may explain why many investigators have failed to find or have denied the existence of capillary congestion in shock. Mild or moderate anesthetic doses of these drugs do not cause a significant degree of visceral congestion,⁷ but, as was demonstrated, lethal amounts do.

Since visceral congestion, if sufficient in degree leads to a reduction in the circulating blood volume or the venous return, the development of capillary congestion after lethal doses of certain chemical substances (pentobarbital, procaine, sodium cyanide and ether) and asphyxia suggests that the engorgement of the viscera may play an important role in the mechanism of death. As was demonstrated, the amount of congestion was fully as great in some instances as after thermal trauma. This raises the question of whether a shocklike process is not implicated in the mechanism of death after the administration of the chemicals investigated.

It may be possible to go a step further. Death from many causes may be accompanied by a significant degree of visceral congestion which the pathologist is unable to evaluate because of the factors mentioned. If the human heart is removed immediately after death from a large variety of causes it may with perfusion, be made to beat again, and this would indicate that the immediate cause of death was not failure of the heart. Is it not possible that in a wide variety of preagonal states due to infectious intoxications and so forth the sequestration of blood in atome visceral capillaries may initiate a shocklike process which constitutes the final disorder of function which precedes and is the final cause of death?

SUMMARY

It was found that asphyxia and lethal doses of pentobarbital ether, procaine, and sodium cyanide cause visceral hyperemia in a degree comparable in some instances to that which develops after fatal thermal trauma.

When a pathologist is called upon to decide whether or not hyperemia is present in the viscera of a shocked organism, he should bear in mind the results of comparative examination of organs after exsanguination and the fact that visceral congestion may be present after death from many causes other than classic shock, especially in organs of control animals sacrificed by lethal doses of anesthetic and other compounds.

It is suggested that the failure of some investigators to find unusual capillary hyperemia in shock is due to the visceral hyperemia which they have observed in control or nonshocked animals sacrificed by methods which in themselves cause intense visceral hyperemia.

We wish to extend our thanks to Dr Ben Sacks for valuable aid in the preparation of this manuscript.

THE MECHANISM OF BACTERIA-INDUCED SHOCK RESULTING FROM CRUSHING OF MUSCLE IN DOGS

H E KRUGER AND MYRON PRINZMETAL, M D
LOS ANGELES, CALIF

IN PREVIOUS studies, shock was induced in dogs by the crushing and replacement of surgically excised muscle. It was demonstrated that bacterial contamination of the traumatized muscle was responsible for the shock state, because, if bacterial growth was inhibited by suitable antibacterial agents, shock was prevented¹. The amount of edema in the traumatized parts was too small to account for the development of shock.

In a series of experiments in rats and mice it has been shown that visceral congestion, due to atony of the vessels comprising the capillary bed, is a major factor in the initiation of the shock syndrome which develops after thermal trauma². This factor operates by sequestration of blood in the dilated and atonic vessels of the visceral organs, which is demonstrable in exsanguinated animals or organs,² as a result of which the effective circulatory volume and the venous return fall to shock levels. In effect, the animal bleeds into its own capillary bed. In certain circumstances, local fluid loss is also a factor.

The purpose of the present investigation was to ascertain whether the factors operative in shock due to muscle crushing¹ are the same as those in thermal shock. Accordingly, experiments were conducted to determine whether the toxic factor from crushed injected muscle leads to capillary atony and a reduction in bleeding volume.

METHODS

The quadriceps femoris of dogs anesthetized with sodium pentobarbital was removed from one hind limb. The muscle was cut into fine pieces, ground in a sterile mortar, and replaced in its original bed. The amount of muscle crushed corresponded to 3 to 5 Gm per kilogram of body weight. Sterile precautions were observed throughout. Experiment 1 As described in previous reports,^{1,3} animals subjected to this procedure were obviously in shock at the end of twenty four hours. There was a decrease in the circulatory volume, the limb operated upon was edematous, and, despite the sterile technique, the crushed muscle at autopsy always had a foul odor, gas was often present, and direct smear of the muscle revealed numerous bacteria of many types.

Bleeding Volume—Under sodium pentobarbital anesthesia the femoral artery was cannulated and the blood received in a weighed container until exsanguination was complete. The bleeding volume is expressed as the weight of blood obtained as a per cent of the body weight.

Hemoglobin Determination—The amount of hemoglobin retained in two test organs, the kidney and the liver, after exsanguination of the animal was used as an index of the degree of capillary atony in the viscera. Hemoglobin was extracted from the finely cut organs with 20 per cent urea solution and readings were made on the Fisher Electro Hemometer. A more satisfactory method of determining hemoglobin in tissues has been developed subsequently and is described in detail in another publication.⁴

Histologic Examination—The method of staining the tissues to facilitate the identification of the erythrocytes and the procedure for making capillary counts are described in a previous publication

Experiment 1—Under sodium pentobarbital anesthesia twelve dogs weighing from 7.8 to 17.2 kilograms were subjected to the crushed muscle procedure. Upon the development of profound shock (twenty to forty hours after the operation) each animal was reanesthetized and exsanguinated and the bleeding volume was determined. Sections of various organs (heart, liver, kidneys, spleen, adrenals, intestines and lungs) were taken for histologic study, and hemoglobin determinations were made of the liver and kidneys of each animal. For comparison, an equal number of normal animals was exsanguinated and investigated in the same manner.

Fig. 1—Graph showing relation of bleeding volume and hemoglobin retention in the liver and kidneys of dogs in shock produced by muscle crushing. Bleeding volume is expressed as the per cent of blood weight to body weight. Hemoglobin retention is in arbitrary units based on retention by normal tissue as unity. The large dots, square and circle represent the average of the values graphed. The vertical lines through these points are equal in length to 2 times the standard deviation and the horizontal lines above and below these represent the standard error of the mean.

In the shock experiments bleeding volume was significantly reduced and retention of blood in the liver and kidneys after exsanguination was significantly increased.

Results—The bleeding volumes of the shocked animals ranged from 0.53 to 3.2 per cent of body weight (mean 2.2 per cent) and those of the control normal animals from 4.3 to 6.6 per cent (mean 5.6 per cent) (Fig. 1). These values for the bleeding volume in normal and shocked dogs are similar to those reported by other investigators.⁵ The hemoglobin content of the kidneys and liver of shocked animals was considerably greater than that of the corresponding organs of normal control dogs (Fig. 1). Histologic examination revealed that the number of open capillaries in the organs of shocked animals was increased.

and that the capillaries were wider and contained more erythrocytes than the corresponding organs of normal control animals. The examiner, without knowing which particular slide he was studying, was able in each instance to identify the organs of the shocked animals by the appearance of the capillaries.

In this experiment the physiologic changes which accompany shock, that is, visceral congestion and reduction in bleeding volume, are similar to those demonstrated in mice and rats after thermal trauma. In both instances a circulating chemical factor is responsible for the observed capillary atony. In the muscle-crushing experiment, this factor, a product of bacterial contamination, may be a bacterial toxin.^{10, 11}

Experiment 2—The following experiment was performed on four dogs in which each animal served as its own control. Under sodium pentobarbital anesthesia the left kidney of each animal was removed and the organ allowed to self-exsanguinate for twenty minutes. After exsanguination was complete, it was weighed, sections were taken for histologic study, and the hemoglobin content was determined. The muscle-crushing procedure was carried out immediately after nephrectomy. Approximately thirty hours later, while the animal was in profound shock, the opposite kidney was removed under sodium pentobarbital anesthesia and investigated in the same manner as the control kidney. The bleeding volume was measured immediately after the removal of the second kidney.

Results In each instance the kidney removed after the animal had entered into shock was more congested than the control kidney, it contained, on an average, more than twice as much blood as the normal kidney, and histologic study showed a large increase in the number of open capillaries, together with an increase in the diameter of and the amount of blood in every capillary. In three of the shocked animals the kidney weighed from 54 to 133 per cent more than the normal control kidney, and in the fourth animal the weights were the same, although the second kidney was more congested than the first. The bleeding volume in the shocked animals varied between 18 and 26 per cent of the body weight. This experiment, like the previous one, shows that a major factor causing the decreased bleeding volume in shock after muscle crushing is congestion of the visceral organs resulting from atony of the vessels comprising their capillary beds.

DISCUSSION

The results of Experiments 1 and 2 clearly indicate that shock due to muscle crushing results from a reduction in the effective circulatory volume and that a principal cause of this reduction is visceral congestion due to capillary atony. Thus, the shock-producing mechanism in crushed muscle injuries is similar to that observed in burns, except that in the former instance the toxic factor which leads to capillary atony is derived from infected muscle tissue. Shock induced by thermal injury in mice is due to a toxic factor not of bacterial origin because the shocked state may occur within a few minutes after severe injury.² Furthermore, the administration of antibacterial substances has no effect on the mortality after thermal injury.^{10, 11}

THE MECHANISM OF DELAYED DEATH FOLLOWING THERMAL TRAUMA

H. C. BERGMAN, PH.D., H. E. KRUGER, AND MYRON PRINZMETAL, M.D.
LOS ANGELES, CALIF.

IN PREVIOUS observations it was shown that burn shock was accompanied by a reduction in the circulatory blood volume, as represented by the bleeding volume, and that two major factors were implicated in this reduction—one, local fluid loss, and the other, atony of the vessels comprising the capillary bed of the visceral organs.¹ One of the methods employed for estimating the degree of capillary atony was measurement of the amount of hemoglobin retained in a test organ. In previous experiments it was shown that after a severe and fatal burn there is a progressive diminution in the bleeding volume, whereas after a less extensive burn there is an initial decrease followed by a gradual increase in bleeding volume as the animal recovers.¹

In view of the fact that most of the previous observations were not carried beyond a twenty-four hour period,¹ it was considered of interest to ascertain whether any of the animals would succumb after apparent recovery from the initial period of shock. Observations showed that a number of animals died at various time intervals, from the second day to more than a month later, and an investigation was undertaken to determine the bleeding volume and degree of capillary atony in surviving animals in an endeavor to elucidate the mechanism of delayed death after thermal trauma.

METHODS

The bleeding volume¹ was ascertained by cutting out the heart of the etherized animal and mopping up the blood entering the thoracic cavity with weighed cotton pledgets. The presence and degree of capillary atony were determined by measuring the amount of hemoglobin retained in the liver. Briefly, the method consists of extracting the hemoglobin from the finely cut liver with a buffered salt solution and measuring it photometrically after conversion to cyanmethemoglobin. The tissue hemoglobin values were corrected for polycythemia and anemia, respectively. Other details of the method have been described elsewhere.^{1,2}

All animals were placed upon a diet of Alber's Friskies, with the daily addition of 10 mg of ferrous sulfate, 0.2 mg of manganese chloride, and trace amounts of cobalt and copper salts per 100 ml of drinking water. These salts were added in an effort to counteract the anemia which was found to develop after the initial period of hemoconcentration in burned rats. In previous observations it had been shown that this diet with the salts added did not influence the bleeding volume.

Experiment 1. Bleeding Volume and Hemoglobin Retention in Mice at Various Time Intervals After Thermal Injury—Each of 412 adult male Swiss mice was anesthetized with ether and immersed up to the head in water at 60° C for seven seconds. The type of burn chosen was one which would permit most of the animals to survive for days or weeks after the initial period of shock. At intervals of two to eight hours during the first twenty-four hours, at the end of two and four days, respectively, and thereafter at stated intervals, a group of surviving mice were etherized and the bleeding volume and amount

of hemoglobin retention in the liver ascertained. Upon each occasion when these determinations were made, control observations were taken upon a group of normal, unburned mice. The number of animals in the burned group which died each day was recorded and a mortality curve constructed (Fig 1).

Fig 1—Time mortality curve based on (●) 300 mice scalded to the head in water at 60° C for seven seconds and (○) 80 rats scalded to the head in water at 65° C for ten seconds.

Results The changes in the bleeding volume and the amount of hemoglobin retention in the liver are shown in Figs 2 and 3. The greatest decline in the bleeding volume was noted in animals which were sacrificed four hours after the burn, at which time the value fell to an average of $2.89 \pm 0.16^*$ per cent of body weight, as compared with the average control figure of $5.86 \pm 0.10^*$. It should be noted that the relatively mild type of burn employed in this experiment does not lead to the severest form of shock.³ By the end of twenty-four hours the bleeding volume was back to almost normal. At the end of two hours the amount of hemoglobin retained in the liver was an average of 1.90 times that in the control, and at the end of four hours, 1.54. By the end of ten hours there was no longer an increased hemoglobin retention showing that the toxic vascular factor was no longer operative. In the subsequent observations, ending thirty-seven days after the experiment was begun, the figures for the bleeding volume returned to normal and there were no further increases above normal in the amount of the hemoglobin retention. Many of the values for hemoglobin retained in the liver fell below normal after the first day. Most of the animals became anemic and all the animals lost weight. A number which died during

* Standard error of the mean.

Fig 2—Relation of bleeding volume and hemoglobin retention to time after thermal injury (initial twenty-four hour period) Based on 100 mice which were immersed up to the head in water at 60° C for seven seconds. The verticle lines through the circles have a total length equal to three times the standard error of the mean. The numbers next to the circles represent the number of mice averaged for each point. For the hemoglobin retention graphs of this figure and Fig 3 the tissue hemoglobin of the burned animals was corrected by the ratio of the hematocrits of normal to burned animals. Within four hours after thermal injury the bleeding volume fell to a minimum value and the hemoglobin retained by the liver had already reached a maximum.

Fig 3—Relation of bleeding volume and hemoglobin retention to time after thermal injury (over a period of thirty-seven days) Based on 212 mice subjected to thermal injury. This is an extension of Fig 2 (the symbols are explained in the text of Fig 2). The dotted lines accompanying the normal curve for the bleeding volume are separated by a distance equal to three times the standard error of the mean. During the thirty-seven days after thermal injury the bleeding volume returned to normal in about thirteen days although the amount of hemoglobin retained by the liver appeared to be somewhat less than normal in the burned mice.

the observation period showed infection or gangrene or both, in one or more limbs. The mode of death was in sharp contrast to that of animals which succumb to burn shock. In the latter instance, the skin temperature falls, dyspnea develops, and death occurs after a period of progressive asthenia and stupor. In the foregoing experiment, many of the animals appeared to be in good condition until very shortly before death and none died with the classic symptoms of shock.

Experiment 2 Rate of Mortality and Bleeding Volume After Thermal Injury in Rats—A group of 80 Long Evans rats, weighing from 250 to 400 grams, were anesthetized with ether and immersed in water at 65° C up to the head for ten seconds. This group together with an equal number of normal unburned rats was placed on the diet described under methods. The animals were observed for twenty six days. A mortality record was kept and a time mortality curve constructed. On the twenty sixth day all the surviving rats were anesthetized with ether and the bleeding volume was determined. Control observations were made upon an equal number of unburned animals.

Results In the rats which had survived for twenty six days the average bleeding volume was $4.94 \pm 0.09^*$ in the controls. Statistical analysis shows that the amount of increase over the control is significant.

A few of the rats developed infection and gangrene of one or more limbs. As in the instance of the burned mice, a number of rats which succumbed at various time intervals after recovery from the initial period of shock appeared in good condition until shortly before death. The time mortality curve is given in Fig. 1.

DISCUSSION

These observations indicate that in mice which survive burn shock the bleeding volume returns to normal after twenty four hours, confirming previous studies with this type of burn.¹ Moreover, there was no increased retention of blood in the liver by the end of ten hours, suggesting that the toxic factor which causes atony of the vessels of the capillary bed was no longer operative. As the mortality curve (Fig. 1) shows, a certain number of mice died from two days to more than thirty days after the trauma. Surviving animals were selected at random for sacrifice on a particular day for determinations of the bleeding volume, but in order to ascertain whether the values in moribund animals differed from those in nonmoribund animals a number of the former were tested at the same time. The values did not differ significantly in the two groups. Neither decreased blood volume nor evidence of capillary atony was demonstrated in any of the animals which survived beyond the initial twenty four hour period.

Wilson and co-workers⁴ followed the clinical course of treated burns in human beings and attributed the delayed deaths in their series to the presence of acute or septic toxemia, rather than to shock. The experiments reported in the present communication clearly show that delayed death in burned mice is not due to shock in the sense of a syndrome accompanied by decreased circulating blood volume and capillary atony.

Whereas the values for the bleeding volume returned to normal in the experiments on mice, the values were found to be above normal in rats which sur-

* Standard error of the mean

vived twenty-six days after thermal trauma. Noble and Collip,^{5, 6} who produced shock in rats by traumatizing them in a specially constructed drum, showed that animals which had been previously subjected to this form of trauma were able to withstand a second trial without being thrown into shock. These authors were unable to explain the immunity which had developed. If an increased blood volume were to be found in these animals, it would help to explain the immunity in the Noble-Collip experiments.

In the absence of visceral congestion and a decrease in the circulating volume, it is necessary to search for causes other than shock to explain the delayed mortality after thermal trauma. Surviving animals develop anemia and loss of weight and not infrequently infection or gangrene of the limbs. Whether the fatal outcome is a result of infection, a metabolic or nutritional disturbance, or is due to some other undetermined cause remains for future studies to explore.

SUMMARY AND CONCLUSIONS

The mechanism of delayed death in burned animals was investigated. The type of thermal trauma chosen for the experiment was one which produced shock but which enabled a large number of animals to survive for a number of days or weeks after the initial period of shock. Observations were made upon the circulatory blood volume, as represented by the bleeding volume, and on the degree of capillary atony, as represented by the amount of hemoglobin retained in the exsanguinated liver. These observations were begun two hours after the burn and continued for a period of thirty-seven days.

In mice, capillary atony and a decreased blood volume were demonstrated during the period in which the symptoms of shock were present. Upon the subsidence of these symptoms (generally within twenty-four hours), the blood volume was restored to its normal value, the capillary atony disappeared, and there was no further reduction in the blood volume or reappearance of visceral congestion throughout the period of observation.

In experiments on rats after similar thermal trauma, the bleeding volume showed a small but significant increase above the normal in observations made twenty-seven days after the burn. A possible explanation for the immunity to shock in the Noble-Collip experiment was suggested.

Delayed death after the type of thermal injury employed is not due to persistent or recurrent shock.

We wish to extend our thanks to Dr. Ben Sachs for valuable aid in the preparation of this manuscript.

LABORATORY METHODS

A SIMPLIFIED SEDIMENTATION RATE TECHNIQUE WITH COMBINED CHART AND CORRECTION NOMOGRAM

NELSON K. ORDWAY, M.D. * AND RICHARD B. SINGER, M.D.
PHILADELPHIA, PA.

THIS paper describes a sedimentation chart and technique that permit correction for the effect of variations in red blood cell plasma ratio on the sedimentation rate. The method of correction by means of a nomogram printed directly on the sedimentation chart, is a simplified adaptation of that of Rourke and Ernstene.¹ The sedimentation chart (Fig. 1) is designed for inclusion in the patient's permanent record.

PRINCIPLE OF METHOD

The sedimentation curve of uncoagulated blood obtained by plotting against time the settling of the topmost layer of cells in a vertical tube is typically sigmoid and may be divided into three components: (1) an initial slow phase or period of aggregation during which rouleau formation takes place and the rate of fall gradually increases; (2) a period of constant and maximum rate of fall, represented by a straight line; (3) a period of packing in which the rate becomes progressively slower as the cells pile up on the bottom of the tube. Sedimentation rate is sometimes defined as the total distance of settling in an arbitrary length of time, usually one hour. This almost always implies a summation of the first two or all three of the phases of sedimentation into a single value which may be the same for entirely different curves. The unambiguous definition of sedimentation rate as the maximum rate of fall, expressed by the slope of the second, straight line portion of the curve has been adopted here.

It is possible to distinguish an elevation in sedimentation rate due to pathologic increase in certain constituents of the plasma, notably fibrinogen from that brought about simply by anemia. Such a differentiation is customarily made by expressing the sedimentation rate of a blood sample as that which would be observed at an arbitrary standard packed cell volume: the effect of variations in the cell plasma volume relationship is thereby eliminated. The two most frequently employed techniques involving a correction of this sort are those of Rourke and Ernstene¹ and Wintrobe and Landsberg.² In the latter method the number of millimeters of sedimentation in one hour is corrected for variations from a packed cell volume of 42 or 47 per cent: the average values for

women and men, respectively. It has been shown that correction is more nearly accurate if based on the maximum rate of fall,³ as in the method of Rourke and Einstene. In their technique, correction is made in the case of either sex to a packed cell volume of 45 per cent by means of a contour line chart constructed from experimental data. The method presented here is virtually the same, the only essential difference being in the simplified calculation of corrected rate through the use of a nomogram derived from the Rourke-Einstene chart.

TECHNIQUE

For use as anticoagulant a solution is prepared of the double oxalate mixture of Heller and Paul⁴ by dissolving 4.43 Gm. of potassium oxalate and 6.87 Gm. of ammonium oxalate (the monohydrate salt in each case) in distilled water to make a final volume of 500 cubic centimeters. This anticoagulant is cheaper and more stable than heparin and unlike the latter has no effect on the sedimentation rate.³ One tenth cubic centimeter of the described 2 per cent solution corresponding to 2 mg. of the salt mixture, is the optimum amount to prevent coagulation of 1 cc. of blood. Small tubes or bottles are prepared by measuring into them and evaporating to dryness appropriate amounts of the solution (for example, 0.3 cc. for 3 cc. of blood). From 67 to 200 per cent of the designated optimum amount of blood may be used without clotting or alteration of packed cell volume or sedimentation rate³ (namely 2 to 6 cc. in the example given), this is a margin of safety useful in clinical work.

The appropriate measured amount of blood should be mixed with the anticoagulant as soon as possible after venipuncture.^{*} Within ninety minutes a chemically clean, dry sedimentation tube is filled to the 10 cm. mark by means of a long stemmed capillary transfer pipette. The sedimentation in millimeters is accurately estimated at intervals of two, four, or six minutes depending on the speed of settling: the more rapid the sedimentation, the shorter is the period of constant fall, and hence the more frequently must observations be made.† Observations are begun approximately fifteen minutes after filling the sedimentation tube and continue until the trend of the plotted points shows that the third phase of the sedimentation curve has been reached. The tube is then centrifuged until packing is complete—about one half hour at 2,000 to 2,500 revolutions per minute—and the volume of packed red cells is read as percentage of whole blood.

After observations have been completed, a straight line is drawn through the points comprising the second phase of sedimentation. Another line is drawn parallel to the first, passing through the upper left hand corner of the chart (intersection of 0 coordinates) and extending to the scale on the right hand or lower margin, where the uncorrected rate of fall is read in millimeters per hour. Finally a straight line is drawn connecting points on the right and left hand scales of the nomogram, representing respectively the rate of fall and the packed cell volume. The point of intersection of this line with the middle scale indicates the sedimentation rate corrected to the standard packed cell volume of 45 per cent. The technique is illustrated in Fig. 2.

^{*}One cubic centimeter of capillary blood is a satisfactory substitute for venous blood provided a sedimentation tube is used such as the Wintrobe which has a capacity of 0.7 cubic centimeter.

[†]In the presence of marked anemia not only is the rate of fall accelerated but in addition the top of the cellular layer is indistinct, due to the increased prominence of the effect of differential settling of erythrocytes in this zone. Precise individual readings are thus not possible but the rate of fall can be accurately estimated if many points are plotted.

Fig 2—Effect of transfusion of washed erythrocytes on the sedimentation rate of a six month-old female infant with nutritional anemia A, Before transfusion B, two days later following transfusions

Up to twelve curves can be plotted concurrently by filling all the tubes and starting the observations approximately fifteen minutes after filling the first. Readings are plotted on a separate chart for each sample. A single observer needs only one stop watch or clock for the whole series of tubes, since they can be read in the same sequence each time.

The procedure is carried out at room temperature. The sedimentation tubes must be 3 mm or more in inside diameter³ and are calibrated to contain a blood column 100 mm in height. Wintrobe⁵ or Rourke-Einstene¹ hematocrits are satisfactory; a higher degree of accuracy in reading is possible with the former. It is important that the rack in which the tubes are set be stable and capable of being leveled so that the tubes are absolutely vertical. It should be placed at eye level to avoid errors of parallax. The tubes should be cleaned with acid

cleaning fluid frequently, preferably after each determination. After thorough rinsing with distilled water they should be allowed to dry by drainage and evaporation, rapid drying with alcohol and ether leaves a surface film which may produce retarded and irregular sedimentation.

SEDIMENTATION CHART AND NOMOGRAM

The sedimentation chart is represented in Fig 1*. As printed it contains on the reverse side a brief description of the method. The construction of the nomogram was made possible by a transformation of coordinates so that the curved contour lines of the Rourke Ernstene chart could be plotted as a series of straight lines. The accuracy of the transformation is shown by the fact that values for corrected sedimentation rate obtained by the nomogram agree with those obtained by the Rourke Ernstene chart within 2 mm per hour except for packed cell volumes near 55 per cent where the deviation may be twice this amount. Values for corrected rates of less than 5 mm or more than 110 mm per hour, the limits of the scale, are rarely encountered.

Fig 3—Transformation of coordinates of Rourke Ernstene chart. The straight lines represent corrected sedimentation rate in millimeters per hour.

DETAILS OF CONSTRUCTION OF NOMOGRAM

Simultaneous values for packed cell volume, rate of fall, and corrected sedimentation index were taken from the Rourke Ernstene chart and assembled in tabular form. The second and third variables were expressed in millimeters per hour instead of millimeters per minute. Corrected sedimentation index is hereinafter referred to as corrected sedimentation rate.

A method of graphic presentation was next sought that would permit plotting corrected sedimentation rate in terms of the other two variables in such a manner that the locus of the points representing any particular value for corrected sedimentation rate would be a straight line. By trial and error and inspection of the plotted points it was found that this could be accomplished most closely when $\log (85 \text{ minus packed cell volume})$ was plotted against $\log (\text{rate of fall})$. The technique is illustrated in Fig 3 in which five

representative values for corrected sedimentation rate have been plotted in terms of packed cell volume and rate of fall. A series of straight lines was obtained for corrected sedimentation rates of 5 through 110 mm per hour. All lines were drawn by inspection.

From this series of straight lines, adjusted values for packed cell volume and rate of fall were obtained and tabulated. It is apparent from Fig 3 that the necessary adjustments were virtually negligible except in the case of many points corresponding to a packed cell volume of 55 per cent. The necessity for larger adjustments at this end of the scale explains the lack of uniformly close agreement between the nomogram and the Rouike-Einstene chart in this range, pointed out in the foregoing section.

The nomogram could then be constructed by placing the coordinates of Fig 3 parallel to each other instead of at right angles. The distance between the lines and the length of the scales were chosen arbitrarily. By this maneuver the straight lines representing corrected sedimentation rate became a series of points lying between the parallel scales. Each point in the series was located by the convergence of three straight lines drawn between widely separated positions on the outer scales representing simultaneous values for rate of fall and packed cell volume. Finally a smooth line was drawn by inspection through the series of points thus located.

The limits of the scale representing packed cell volume are 20 and 55, those of the Rouike-Einstene chart. The upper limit of the middle scale is 110, higher values for corrected sedimentation rate cannot be included since they are represented by curves rather than straight lines in the original transformation of coordinates (Fig 3). The lower limit of this scale corresponds to that of Rouike and Einstene. In the scale representing rate of fall, rates below 5 are not included because the nomogram would be made unwieldy, such rates are, in fact, infrequently encountered. Values above 360 represent an extrapolation since this value was the highest employed in the construction of the nomogram.

DISCUSSION

The sedimentation rate of oxalated blood is constant for a period of two and one-half hours following collection of the samples, thereafter there may be a decrease in rate, hence the need for beginning observations within ninety minutes. Zero time on the coordinate chart is quite arbitrary and for purposes of convenience will correspond in most instances to the time of the initial observation. Humps in the sedimentation curve may indicate a dirty tube or hemolyzed or partly clotted blood, the curve should be smooth and sigmoid and the points of the second phase should fall exactly on a straight line. The second phase ordinarily begins fifteen to thirty five minutes after the tube is filled and lasts fifteen to thirty minutes. It is thus necessary neither to start observations at once nor to continue them for a fixed period of time.

The precision of this technique is illustrated by the examples given in Figs 2 and 4. Fig 2 illustrates the effect of a variation in packed cell vol

ume on the observed sedimentation rate, while the corrected rate remains practically unchanged. In Fig. 4 is shown the correspondence of the corrected rates for venous and capillary blood in the same patient.

The corrected sedimentation rate of normal persons varies from 5 to 20 mm per hour, corresponding to a corrected sedimentation index of 0.08 to 0.35 in the Rourke-Ernstene method. Rates between 20 and 45 mm per hour are considered slightly elevated, between 45 and 75, moderately elevated and over 75 markedly elevated.

Fig. 4.—Sedimentation rates of capillary and venous blood samples simultaneously withdrawn

This method has proved its practicability in seven years of use in the Hospital of the University of Pennsylvania.

SUMMARY

The determination of sedimentation rate according to the Rourke-Ernstene technique has been simplified through the use of a report form with nomogram, by means of which the observed rate may be corrected for variations

in packed cell volume from the standard value of 45 per cent. This correction permits a more accurate interpretation of sedimentation rate through the elimination of one extraneous effect, the varying red blood cell plasma ratio.

Dr. David Black proposed the inclusion of slopes on the margin of the coordinate chart to obviate the calculation of the rate of fall. We are indebted to him for this suggestion and for helpful advice in many other matters.

A DEVICE TO FACILITATE THE CLEANING OF CAGES CONTAINING COTTON RATS

R G FISCHER A B
SAN FRANCISCO, CALIF

THE jumping ability of cotton rats is familiar to anyone who has handled these animals. If any appreciable number of cotton rats is in use, the cleaning of cages involves the expenditure of much time and energy.

Fig 1

From the George Williams Hooper Foundation University of California Medical Center
Received for publication Feb 9 1948

The procedure formerly used in the animal quarters of the George Williams Hooper Foundation consisted of placing the cage in a large galvanized garbage can, removing the lid of the cage, placing the rats in the bottom of the can, and then cleaning the cage. After the cage had been cleaned, the rats were caught individually with forceps and placed in the cage. In addition to being time consuming, this procedure occasionally was responsible for rupture of the spleen or liver of the animals.

Hence, to facilitate cleaning the cages, the device shown diagrammatically in Fig. 1 was made. It is easily made with readily available materials. It is used with cages of the usual type, which have the lid on top. The device consists essentially of a metal box with tapered sides and with a simple sliding floor or stout canvas or flexible metal screen. No dimensions are given here, since it is necessary to adapt the size of the apparatus to the size of the cages in use.

In operation, the device is dropped into the cage by sliding it under the lid of the cage as the lid is raised. With the rats under the device, the lid of the cage is removed completely and the sliding floor is pulled into position. The device containing the rats, is then lifted from the cage. After the cage has been cleaned and fresh bedding and feed have been supplied, the rats are quickly and easily returned to it by means of the sliding door at the broad end of the device.

Under actual conditions of use, an experienced animal keeper required slightly less than one minute per cage to clean a total of 182 cages. Without the facilitating device, the same worker required about three minutes per cage.

PENICILLIN IN THE TREATMENT OF ACTINOMYCOSIS

DONALD R. NICHOLS, M.D., and WALLACE L. HERRELL, M.D.
ROCHESTER, MINN.

IN 1943 Florey and Florey¹ reported the results of the treatment with penicillin of two patients who had actinomycosis. In these patients penicillin appeared to have no effect on the infection. However, in the light of our present knowledge the amounts of penicillin used and the method of administration employed appear to have been inadequate. In 1943 the Committee on Chemotherapeutic and Other Agents of the National Research Council² also reported data on the use of penicillin in three patients who had actinomycosis. One patient improved and two died. No details as to the type of case or the method or duration of treatment were given. In 1944, in collaboration with Heilman we³ reported our initial observations on the use of penicillin in the treatment of twelve patients who had actinomycosis. No conclusions could be reached from these limited observations because the patients had been followed for inadequate periods. Treatment with penicillin of small groups of patients who had actinomycosis has been reported by other investigators.^{4,5} The results have been encouraging.

Up to the present time, sixty patients who had actinomycosis have been treated with penicillin under our supervision. Fourteen of these patients have not been followed for a sufficient length of time to enable us to evaluate the results of treatment. Our present report, therefore, deals with our observations on the use of penicillin in the treatment of forty-six patients who had actinomycosis. These forty-six patients have been followed for periods of from one to five years since the conclusion of the treatment.

Considerable confusion and difference of opinion exist concerning the definition of the term actinomycosis. For the purposes of our investigative work we have confined our studies to infections caused by the microaerophilic organism *Actinomyces bovis*. Infections caused by the several species of the genus *Nocardia* have been classified separately and are not included in this report. The diagnosis of actinomycosis in each of our patients was made by direct examination or culture of pus obtained from a draining sinus or from material obtained at operation. All strains of *Actinomyces bovis* cultured were found to be sensitive to penicillin in vitro, the organism being inhibited by 0.01 to 0.1 unit of penicillin per cubic centimeter of culture medium.

In attempting to evaluate methods of treatment it is of importance to qualify carefully the general term actinomycosis, for the prognosis varies greatly according to the location of the lesion, the duration of the infection and the

Received for publication Jan. 26, 1948.

general condition of the patient. A method of treatment which is effective when the soft tissues of the face and neck are involved is often entirely ineffective when actinomycosis involves other parts of the body. If the disease has been present sufficiently long to permit an overgrowth of fibrous tissue or an impairment of the general health of the patient, effective treatment of any type will be much more difficult. A classification of actinomycosis according to the organ or organs involved is the most desirable. However, inasmuch as the pathologic process and the prognosis are similar when certain regions of the body are invaded, for purposes of discussion a more general classification can be adopted. Our patients, therefore, have been grouped under five general headings: cervicofacial actinomycosis, pulmonary actinomycosis, abdominal actinomycosis, pelvic actinomycosis, and actinomycosis involving other parts of the body.

Of the group of forty-six patients on whom we are reporting data, twenty-six were suffering from cervicofacial actinomycosis, nine from pulmonary actinomycosis, eight from abdominal actinomycosis, and three from pelvic actinomycosis. Penicillin was administered to each of these patients either by intermittent intramuscular injections every three hours or by the continuous intravenous drip method. The dosages of penicillin varied widely between 80,000 and 1,000,000 units daily. In most cases penicillin was administered continuously for periods ranging from two to seven weeks. In some instances the penicillin was administered in courses of ten days each, with intervals of one to several weeks intervening.

RESULTS ACCORDING TO LOCATION

Cervicofacial Actinomycosis.—Twenty-six patients with cervicofacial actinomycosis received penicillin. Since 1940, twenty-five other patients with cervicofacial actinomycosis have been seen by our colleagues or by ourselves. These patients did not receive penicillin but were treated by other methods. The number of patients who recovered was approximately equal in both of these groups, that is, in excess of 90 per cent (Table I). The significant difference between the two groups, however, appears to be the duration of treatment necessary to bring about recovery. When penicillin was used, satisfactory results were obtained after an average period of treatment of less than two months. When penicillin was not used, it was necessary to continue the treatment, on an average, for nearly six months. These figures include the entire period from the onset of treatment to the discontinuance of all forms of therapy. In both groups treatment was carried out continuously in some cases and at varying intervals in others.

TABLE I. PENICILLIN THERAPY FOR CERVICOFACIAL ACTINOMYCOSIS

TREATMENT	NUMBER OF CASES	RECOVERY		FAILURE		AVERAGE DURATION OF TREATMENT (MO.)
		NUMBER	PER CENT	NUMBER	PER CENT	
Penicillin	26	24	92	2	8	1.5
No penicillin	25	24	96	1	4	5.9

Pulmonary Actinomycosis—The most striking results of treatment with penicillin occurred in the patients who had pulmonary, abdominal, or pelvic actinomycosis, since patients with these types of actinomycosis had uniformly poor prognoses when other types of treatment were used. Nine patients who had pulmonary actinomycosis received penicillin (Table II). In this group there were five recoveries and four failures. Since 1940 thirteen other patients who had pulmonary actinomycosis have been seen by our colleagues or ourselves. None of these patients received penicillin but they were treated by other methods. Only one of them appears to have recovered.

TABLE II. PENICILLIN THERAPY FOR PULMONARY ACTINOMYCOSIS

TREATMENT	NUMBER OF CASES	RECOVERY		FAILURE	
		NUMBER	PER CENT	NUMBER	PER CENT
Penicillin	9	5	56	4	44
No penicillin	13	1	8	12	92

Abdominal and Pelvic Actinomycosis—Eight patients who had abdominal actinomycosis and three patients who had pelvic actinomycosis received penicillin (Table III). Six of those who had abdominal actinomycosis recovered and two did not. All of those who had pelvic actinomycosis recovered. Of sixteen patients with abdominal actinomycosis who did not receive penicillin only three appear to have completely recovered.

TABLE III. PENICILLIN THERAPY FOR ABDOMINAL AND PELVIC ACTINOMYCOSIS

TREATMENT	NUMBER OF CASES	RECOVERY		FAILURE	
		NUMBER	PER CENT	NUMBER	PER CENT
Penicillin	11	9	82	2	18
No penicillin	16	3	19	13	81

COMMENT

The results of this study appear to indicate that penicillin is an effective agent in the treatment of actinomycosis, its effectiveness varying somewhat with the location of the lesion. As is true in most infections, actinomycosis varies greatly in different individuals. Apparently in some cases of mild actinomycosis complete recovery from the infection occurs without treatment.¹⁰ How often spontaneous recovery occurs is difficult to determine for it is not until the disease has become quite extensive that a clinical and bacteriologic diagnosis can be made. However, when the infection has become well established spontaneous cures occur only rarely.

Cervicofacial actinomycosis has responded well to several methods of treatment.¹¹ Prolonged surgical drainage, roentgen therapy, and administration of the iodides and some of the sulfonamide compounds have proved of value in the treatment of actinomycosis when it involves the neck or face. However, penicillin appears to have definitely shortened the duration of the infection and the period of treatment. In cases of cervicofacial actinomycosis of short duration

the use of penicillin alone has resulted in cures. When the infection has been extensive and of long duration, use of penicillin has been combined with surgical treatment. In most of the cases in which penicillin has been used, the sinuses closed rapidly and the patients recovered completely in a relatively short time. Even the two patients who did not recover completely improved markedly while under treatment. Drainage from the sinuses ceased entirely, and the infection appeared to be cured at the time treatment was discontinued. However, in these two patients evidence of active infection appeared again several months later.

In some cases of cervicofacial actinomycosis death occurs from extension of the infection into the meninges. One of our patients was critically ill, with evidence of meningitis secondary to cervicofacial actinomycosis. Penicillin was administered for six weeks and the patient recovered.

Pulmonary actinomycosis nearly always has been a progressive and fatal disease. The prognosis has been particularly unfavorable when the parenchyma of the lung has been invaded. The usual methods of treatment have been ineffective in most cases. The recovery, after treatment with penicillin, of five of our nine patients who had pulmonary actinomycosis is, therefore, most encouraging. Moreover, two of the patients for whom the results are listed as failures are in good general condition, although they still have evidence of active disease.

Abdominal actinomycosis has always been a serious disease, but good results have been obtained in occasional patients by several different methods of treatment.¹² However, the percentage of patients who recovered has never been very great and the prognosis, therefore, has been poor. Seventy-five per cent of the patients with abdominal actinomycosis who received penicillin recovered. It appears, therefore, that penicillin is a very effective chemotherapeutic agent in the treatment of abdominal actinomycosis.

Actinomycosis involving the pelvic viscera in women may well be merely a localized form of abdominal actinomycosis. However, the prognosis when actinomycosis involves the pelvic organs has been extremely poor, and very few recoveries ever have been reported. The recovery, therefore, after treatment with penicillin, of the three women who had actinomycosis involving the pelvic viscera seems particularly significant.

In the treatment of all types of actinomycosis, a dosage of at least 500,000 units of penicillin daily administered intramuscularly or intravenously for a period of six weeks appears to achieve the best results. Adequate drainage is indicated if abscesses are present.

Because we have been attempting to evaluate the effectiveness of penicillin in the treatment of actinomycosis, other forms of therapy, aside from surgical drainage or excision of diseased tissue, have been avoided so far as possible in the treatment of our patients. It seems possible, therefore, that even better results can be achieved in the future if administration of adequate amounts of penicillin is combined with the use of sulfonamide compounds or of streptomy-

SUMMARY

Forty six patients who had actinomycosis were treated with penicillin and have been followed for periods of from one to five years. Of twenty six patients suffering from cervicofacial actinomycosis, twenty four had excellent results. These results were obtained after an average period of treatment of less than two months, a period significantly less than the usual length of time required to obtain comparable results when penicillin was not used. Of nine patients who had pulmonary actinomycosis, five recovered. Of eight patients who had abdominal actinomycosis, six recovered. All three patients who had pelvic actinomycosis recovered. All strains of *Actinomyces bovis* cultured from these patients were sensitive to penicillin *in vitro*. Therefore penicillin appears to be an effective chemotherapeutic agent in the treatment of actinomycosis and a useful adjunct to other forms of therapy.

MATERNAL ISOIMMUNIZATION WITHOUT EVIDENCE OF CLINICAL ERYTHROBLASTOSIS FETALIS IN THE NEWBORN

WILLIAM L. DONOHUE, M.A., M.D., AND I. ARTHUR FRIMES, M.D.*
TORONTO, CANADA

ONE of the many problems which remain to be solved in the field of Rh-Hi isoimmunization or sensitization is why the occasional infant possessing the antigenic factors against which the mother is isoimmunized is born healthy and shows no subsequent evidence of erythroblastosis. Occasionally, in such cases, the concentration of antibodies of both the early immune and hyperimmune type is surprisingly high. An explanation of this phenomenon may possibly furnish a basis for the development of more effective methods of treating the sensitized mother to lessen or abolish the deleterious effects of the antibodies on the fetus.

Instances of normal Rh-positive infants born to mothers isoimmunized against one or more of the factors which the infant has inherited from the father may be divided into two categories:

1. Cases in which the immunization was discovered at or near term with no clear cut history of a previously affected infant.
2. The extremely rare case in which there was a history of a previously affected infant.

Several reports have appeared in the literature of clinically normal Rh-positive infants born to Rh-negative mothers whose blood contained Rh antibodies. In the majority of these reports there was no clear cut history of a previous child suffering from erythroblastosis. Possibly, in these cases, the production of antibodies had been initiated too late in pregnancy to have resulted in significant disease of the fetus or the concentration of antibodies was at no time sufficient to cause fetal damage.

It is probably correct to assume that once isoimmunization against one or more of the Rh-Hi factors has been established, either as a result of pregnancy or transfusion, it is permanent even though the presence of antibodies cannot be detected by present laboratory methods. Experience has shown that in the usual course of events if a mother has been immunized against one or more of the Rh-Hi factors and has borne a child with erythroblastosis, all subsequent infants who inherit one or more of the factors against which the mother is isoimmunized will suffer from erythroblastosis. Furthermore, each succeeding infant is usually affected to a greater degree than its immediate predecessor. Potter,¹ in her monograph, repeatedly substantiates this viewpoint more or less categorically and insists that there are no exceptions to this general rule. She was unable to find any examples in the literature where a normal Rh-positive infant was born to a mother who had previously given birth to an infant suffering from erythroblastosis.

Burnham,² Dockeray and Sachs,³ Goldbloom and Lubinski,⁴ and Kainer and Miller⁵ all have described cases in which apparently normal Rh-positive

From the Laboratory of The Hospital for Sick Children and the Department of Pathology and Bacteriology, University of Toronto.

Aided by a grant from the Banting Research Foundation.

Received for publication Sept. 4, 1947.

*Fellow in Pathology, The Hospital for Sick Children.

infants were born to mothers who exhibited it or non term Rh antibodies. In none of the reports was there conclusive evidence of a previous erythroblastotic infant.

Denny⁶ published an example of severe erythroblastosis in one of Rh positive identical twins, with only mild manifestations in the other. Both of the twins survived. The mother was Rh negative and the father Rh positive. The mother's blood presumably contained antibodies in high titer. The mother's previous obstetric history was as follows. There were four successive normal pregnancies in 1924, 1927, 1929 and 1932. In 1934 she gave birth to twins, one of whom was stillborn, the other lived four hours and died of hemorrhage. In 1936 she gave birth to a sixteen pound stillborn infant and although no data were available, it was presumed that this was a fatal case of fetal hydrops.

Although one might deny that the pregnancies terminating in 1934 and 1936 were concerned with Rh isoimmunization it is difficult to explain the great difference in the degree of involvement of the second set of twins born of the last pregnancy, both of whom survived. The author postulates a greater functional defect in that portion of the placenta serving the twin with the more severe disease. It would seem in this case that other factors besides the duration of action, concentration and type of antibodies influenced the deleterious effect of the antibodies on the fetal tissues. Assuming that the constitutional susceptibility of the identical twins was the same and that the maternal factors were constant for both twins, one has to conclude as did Denny, that the explanation for the variation was a functional difference in the portion of the placenta serving each twin. It appears that the placenta may play a significant role in the protection of the fetus even if isoimmunization has been established.

Cappell⁷ cites an example (Case 10) which is very suggestive of normal Rh positive children being born after erythroblastosis has been established in earlier offspring. But, as Cappell points out, however suggestive the case history may be, the cause of death in the earlier infants was not fully ascertained since postmortem examinations were not done. Cappell also states that Dr. Stimbury⁸ and Dr. Chow⁹ both encountered cases in which a healthy unaffected Rh positive child was born to an Rh negative mother who had previously delivered a child with severe erythroblastosis. The data on the family studied by Stimbury⁸ (Case 3), although very suggestive and probably valid cannot be accepted as definitely proved since the children presumed to have suffered from erythroblastosis antecedent to the normal infant were born prior to the discovery of the Rh factor and it is not stated whether or not a postmortem was performed.

Diamond¹⁰ has seen nine infants who showed no clinical evidence of erythroblastosis although they were all Rh positive and were born to women who were isoimmunized to the Rh factor which their babies had.

The two cases which we are reporting are definite exceptions to the usual experience. Fortunately the opportunity presented itself to study these families in some detail. We believe that enough data were obtained to prove that in each mother may have an erythroblastotic offspring, followed by a healthy infant of

identical or similar Rh pattern. It is felt that this report is important as it establishes the fact that such cases do occur and thus offers some hope that eventually a method of treatment may be discovered whereby the immunized mother can be assured of having a normal Rh-positive baby. As far as we can determine, no unequivocal example similar to ours has yet been published.

CASE 1—Mrs M N, Group O, Rh negative, cde/cde, Mr G N, Group O, Rh positive, CDe/CDe (negative to anti c)

On July 27, 1942, Mrs N was delivered of a full term male infant (P N), Group O, Rh positive, CDe/cde. The infant was said to be normal and healthy but was mildly jaundiced on the second day of life. The jaundice disappeared on the same day without treatment and the child has been perfectly well since. No Rh studies were done on the mother at that time.

On May 30, 1945, Mrs N delivered a Group O, Rh positive (tested with anti D only), full term female infant weighing 6 pounds 12 ounces. Jaundice appeared on the fourth day and became increasingly severe. The infant had peculiar stiffening spells. By the time of admission to the Hospital for Sick Children, on the sixth day of life, the jaundice was extreme. The liver was two fingerbreadths below the right costal margin, but clinically the spleen was not palpated. No nucleated or immature red cells were seen in the blood film. The baby was treated with 100 ml of normal saline and 60 ml of blood of unknown Rh type intravenously. Her condition deteriorated rapidly and respirations ceased seventeen hours after admission, seven days after birth.

The mother's serum, tested six days post partum, showed agglutinating or early immune antibodies against Rh positive cells. Neither titrations nor tests for blocking or hyperimmune type of antibodies were done at this time.

A post mortem examination was performed. The gross findings were severe jaundice, hepatomegaly, splenomegaly, and marked degree of kernicterus of the basal ganglia, moderate edema of the retroperitoneal tissues, and hemorrhages into the lung parenchyma. Microscopically there was a large amount of extramedullary hematopoiesis in the liver, with a lesser amount in the spleen. Numerous macrophages containing blood pigment were present in the liver and spleen. The findings were in all respects typical of erythroblastosis fetalis (icterus gravis).

On May 7, 1946, Mrs N delivered a male full term infant (F N), Group O, Rh positive, CDe/cde. The infant was seen within a few hours of birth by a pediatrician who has a particularly wide experience with erythroblastosis and who, in view of the mother's past history, was expecting the baby to be severely affected. Throughout the infant's normal stay in the maternity hospital there was at no time any clinical evidence of erythroblastosis. The subsequent progress of the child has been normal.

The mother's serum, tested May 16, 1946, nine days post partum, showed blocking or hyperimmune antibodies only, to a dilution of 1:32 against both CDe and cDe cells. Breast milk tested at that time showed the presence of weak antibodies in 1:2 dilution.

Mrs N's serum was again tested January 18, 1947, eight and one half months post partum, and again only blocking or hyperimmune type of antibodies was present to a dilution of 1:4 against both CDe and cDe cells.

CASE 2—Mrs L, Group O, Rh positive, CDe/CDe, Mr L, Group A, Rh positive, cDe/cde *

On March 21, 1940, Mrs L delivered a male infant (H L), Group O, Rh positive, CDe/cDe. The infant survived and was normal. Following delivery the mother required two transfusions. One donor, a brother-in-law, was subsequently found to be Group O, Rh positive, CDe/cDe, and the other was Group O, Rh positive, cDe.

On February 25, 1944, Mrs L gave birth to another boy (I L), Group A, Rh positive, CDe/cDe. The infant survived and was normal.

*Predicted by Dr Louis K Diamond with his anti d serum and subsequently proved by the last child.

On April 1, 1946, the third boy (R L) was born, Group O Rh positive, CDe/cDE. Jaundice was noted at birth and gradually became more severe. Two days after birth the infant was transferred to The Hospital for Sick Children. Examination on admission revealed a severely jaundiced baby with a palpable liver and spleen. The red blood count was 4,300,000 and the hemoglobin 11.9 grams. Blood films showed many polychromatic red cells and 18 normoblasts per 100 white blood cells. The baby received a total of 465 ml of Group O Rh negative blood* in 14 transfusions over a seventeen day period. Plasma and calcium gluconate were also used in the treatment. On discharge at 19 days of age with a hemoglobin of 13.9 grams, the baby appeared cured. Although the mother states the child was physically slightly retarded at first in comparison with her other children, subsequent development has been normal.

The third baby was considered to have been a clinical case of erythroblastosis. The antibodies demonstrated in the mother were anti E both early immune and hyperimmune and anti c hyperimmune only. Antibody determinations on the mother's serum following the birth of this baby and prior to her last pregnancy were as shown in Table I.

TABLE I. ANTIBODY TITER, MRS L'S SERUM USING KNOWN CELLS

5/3/46	0	0	1:64	1:128	-	-	0	1:4

In January, 1947, it was learned that Mrs L was again pregnant and two samples of blood were obtained prior to her delivery on March 6, 1947. The fourth baby was a full term male Group O, Rh positive CDe/cde. Because the child was expected to have a case of erythroblastosis, he was admitted to The Hospital for Sick Children one half hour after delivery and followed closely throughout his eight day stay in the hospital. Results of physical examination, red blood count, hemoglobin, and blood film were normal at all times. On admission the hemoglobin was 22 grams. This fell gradually until the day of discharge when it was 16.7 grams. No treatment was given and the subsequent course and development of the child were normal.

Undiluted cord serum and the infant's serum on admission exhibited weak antibodies against Rh positive CDe/cDE and Rh negative cells. The infant's cells also gave a 4 plus Coombs test.

Antibody determinations during and following Mrs L's last pregnancy are shown in Table II. Unfortunately, blood from the mother in the immediate post partum period was not available.

COMMENT

It is considered that Case 1 is a clean cut example of a normal Rh positive child being born to an isoimmunized Rh negative mother subsequent to the

Preferably this infant should have received CDe/CDe blood but at the time of the child's admission facilities were not available for full investigation of the case or Rh subtyping of the donor's blood.

birth of an infant which suffered from erythroblastosis severe enough to cause death. Agglutinating Rh antibodies were demonstrated following the birth of the second child, and postmortem revealed the cause of death of this child to be erythroblastosis. Rh antibodies of the hyperimmune variety were present following the birth of the last child which was Rh positive and clinically normal. Any explanation in the light of our present knowledge must be pure conjecture. If one believes that fetal erythrocytes must cross the placental barrier to induce isoimmunization, a possible explanation, in view of the relatively low titer of antibodies (1:32) present after the birth of the third and normal child, is that during the third pregnancy the placental barrier was intact at all times and that no fetal cells gained entrance to the maternal circulation to further stimulate the production of antibodies to a sufficient level to cause fetal damage. Against this theory is the fact that the titer is not a reliable index of the amount of damage antibodies may cause. Frequently we have encountered persistently low antibody titers, as determined by the ordinary laboratory methods for the agglutinating and blocking of hyperimmune types, in cases where the infant was stillborn or severely involved.

The circumstances in Case 2 are such that a tentative explanation for the normality of the last baby is possible. The isoimmunization of this Rh positive, CDe/CDe mother which is of a relatively rare type, is a manifestation of an antibody response to two antigens, E and e. If the relative frequency of the occurrence of antibodies is any criterion, E and e must be considered as weak antigens. The necessary Rh and H₁ factors to stimulate the production of the antibodies found in the mother's serum were present in the children of the first three pregnancies all of which were CDe/eDE, and in the two donors, who were CDe/eDE and eDE respectively. Presumably three pregnancies and two transfusions were necessary to stimulate antibody production to a sufficient level to result in a moderately severe case of erythroblastosis. It is possible that the isoimmunization was initiated by the two transfusions following the first pregnancy but the antibody concentration did not reach a sufficient level during the second pregnancy to result in clinical erythroblastosis in that child. During the third pregnancy both anti-E and anti-e were effective against the fetal erythrocytes, the former apparently being the more potent as judged by the titrations. Probably the combined effect of these antibodies, particularly anti-E, was sufficient to result in clinical disease in the infant. In the last pregnancy, resulting in an Rh-positive, CDe/eDe boy, only anti-e was effective against the fetal erythrocytes. Although antibodies could be demonstrated in the infant's serum and adsorbed to his erythrocytes, apparently this one effective antibody was not present in sufficient concentrations to have resulted in any appreciable damage to the infant's red blood cells.

SUMMARY

Two cases are reported of maternal Rh-H₁ isoimmunization which resulted in infants suffering from erythroblastosis, in each case the mother, in a subsequent pregnancy, delivered a clinically normal baby possessing at least one Rh-H₁ factor against which she was isoimmunized.

We wish to acknowledge the kindness of Dr Louis K Diamond, Boston, Mass, for providing us with specific Rh antisera and for checking our results. We are also much indebted to Mrs E M Hutchinson for her able technical assistance.

ANEMIA OF INFECTION

IX INFLUENCE OF ADRENALECTOMY AND OF ADRENAL CORTICAL HORMONE ON HYPOFERREMIA AND OTHER BLOOD CHANGES ASSOCIATED WITH INJECTION OF TURPENTINE

D N MAJUMDER, M D,* AND M M WINTROBE, M D, PH D
SALT LAKE CITY, UTAH

OF THE profound metabolic changes accompanying infection, one which seems to be related to the anemia associated with infection is hypoferrinemia.¹ In view of the role which the adrenal gland has been shown to play in conditions of stress,² it seemed desirable to determine whether or not this gland is concerned with this state of hypoferrinemia. Since a marked fall in plasma iron occurs following injection of either turpentine or staphylococci,³ the former was adopted as the more easily controllable means for producing the hypoferrinemia of inflammation. In addition to observations on the plasma iron in normal and adrenalectomized rats following intramuscular injections of turpentine, changes in hemoglobin and in the total and differential white cell counts are recorded.

MATERIALS AND METHODS

One hundred twenty eight albino rats of both sexes, of Sprague Dawley strain, each weighing between 100 and 200 grams, were used in this study. The animals were divided into several groups as described under Results. Bilateral adrenalectomy was performed by the dorsal route as described by Griffith and Farris,⁴ care being taken to avoid rupture of the capsule and to control bleeding during operation. Following adrenalectomy, these animals were allowed 1 per cent sodium chloride as fluid. The diet otherwise was the same as that of the controls. After seven days, data were secured to establish the range of values for adrenalectomized rats.

Originally it was intended to inject 0.5 ml of turpentine in normal and in adrenalectomized rats. Unlike the normal controls, the adrenalectomized rats could not withstand this dose of turpentine. But three out of seventeen survived for four hours. By a process of trial and error, a dose of 0.1 ml of turpentine per 100 grams body weight was selected as one which could be given to adrenalectomized rats as well as to normal unadrenalectomized rats.

Blood for estimation of hemoglobin and total and differential leucocyte counts was obtained from the tail veins of the animals. For plasma iron determinations, groups of three or four were anesthetized with 0.5 ml of 1 per cent Nembutal per 100 grams body weight in the case of normal intact rats and with 0.4 ml per 100 grams in the adrenalectomized rats. When fully anesthetized, their abdomens were opened and blood was collected from the abdominal aorta in iron free syringes and pooled in iron free centrifuge tubes. Estimation of plasma iron was made from the pooled blood by the method of Barkan and Walker.⁵ Hemoglobin was determined photoelectrically with Evelyn's colorimeter.⁶ Total and differential white cell counts were done by the usual techniques, cover slip preparations being used for the latter purpose.

RESULTS

All data, save for some of the values for plasma iron which consisted of single observations, have been examined by Fisher's *t* test. Mamlund⁸ has pointed out that this is the only valid method for estimating the significance of means when the number of observations in the series is thirty or less.

Observations in Twenty One Normal and Fifteen Adrenalectomized Rats — Data for normal levels of hemoglobin, for total and differential white cell counts and for plasma iron in normal and adrenalectomized rats are presented in Table I. The values for iron were somewhat lower than had been observed in normal rats in previous experiments in this laboratory.⁹ Although monocytes and eosinophiles were encountered in the differential counts values for these have not been entered in the table as they generally were few in number as compared with other cells and nothing striking was found about them. Table I also gives the comparison of the mean values by the *t* test already referred to. Comparing the values of *t* with those at the usually accepted level of significance (that is, probability of 5 per cent) it is seen that a significant increase

in hemoglobin and in neutrophiles was observed following adrenalectomy but no significant changes could be demonstrated in total white cell count, lymphocytes, or plasma iron

Observations on the Effects of Injection of Turpentine in Normal and Adrenalectomized Rats —

1 In a series of twenty one rats, irrespective of individual weights, 0.5 ml of turpentine was injected in the leg. Blood studies were made at intervals of four, eight, twelve, twenty-four, forty-eight, and ninety six hours after injection. Data for plasma iron and hemoglobin obtained from these animals, collected in Table II, show a rise in hemoglobin level reaching its maximum at twelve

hours and a fall in plasma iron reaching its lowest level at twenty four hours. A sudden drop of total leucocytes and lymphocytes, accompanied by a slower drop in granulocytes, is evident from Fig 1, where the values for these have been charted. The significance of these values as compared with data for normal untraumatized controls is indicated in Table III.

2 In a series of twenty-four normal intact rats turpentine was injected in a dose of 0.1 ml per 100 grams. Data from these rats are summarized in Tables IV and V. As can be seen from Fig 2, with this dose normal intact rats reacted in essentially the same manner as those receiving 0.5 ml of turpentine.

The leucocyte curves exhibited more or less the same features as those of rats receiving 0.5 ml of turpentine, the drop in values was, however, less

3 In twenty-four adrenalectomized rats 0.1 ml of turpentine per 100 grams weight was injected and data collected as before. As is evident from Fig. 3, although there was the same tendency toward a fall in plasma iron and a rise in hemoglobin curve within the first twelve hours as in traumatized unadrenalectomized rats, the subsequent changes differed markedly. Thus Table VI brings out the fact that from twenty-four hours and on after injection, the hemoglobin in these animals seemed to be stabilized at a significantly lower level than before injection and, concurrently, there was a definite lag in the rise of the plasma iron curve.

Observations on the Effects of Cortical Hormone on Normal Rats—In a series of twenty intact normal rats adrenal cortical extract* was injected intramuscularly in doses of 10 ml per rat without regard to individual weights. This dose is double that used by Dougherty and White^{10, 12} in their experiments and was chosen advisedly in order to emphasize the effects if any of cortical hormone on the level of plasma iron in rats. As is evident from Fig 4, there

did not seem to be much variation in the levels of plasma iron or hemoglobin. This impression is confirmed also by examination of Table VIII where the values for these rats have been summarized.

The behavior of the leucocytes was very striking however, as is evident from Fig. 4. Within four hours after injection there was a fall in the number of lymphocytes, with a corresponding increase in the number of neutrophils as well as some variation in the total white cells. The significance of these variations is given in Table IX.

DISCUSSION

Neither adrenalectomy nor injection of cortical hormone produced any significant change in the value of plasma iron in normal rats. On the other hand, both in normal intact and in adrenalectomized rats the injection of turpentine was immediately followed by a significant drop in the level of plasma iron. Thus hypoferrinemia following turpentine injection is independent of the presence or absence of the adrenal glands in rats. However the hypoferrinemia seemed to persist longer in adrenalectomized than in nonadrenalectomized rats. Further, in adrenalectomized rats, this prolonged hypoferrinemia was associated with a significantly lower level of hemoglobin. It appears, therefore, that the adrenal gland may be related in some way to the quick recovery from hypoferrinemia which occurs in intact rats injected with turpentine and to the maintenance of the normal hemoglobin level.

Adrenalectomy was followed by a significant rise in hemoglobin values in rats. This was probably due to hemoconcentration which is known to occur in most animals after adrenalectomy. No significant change in hemoglobin was noticed in normal rats on injection of cortical hormone. The immediate effect of turpentine injection on the hemoglobin values of both normal and adrenal ectomized rats was a sudden rise. This was more marked in the normal than in the adrenalectomized rats.

The number of total leucocytes was not significantly altered either by adrenalectomy or by injection of cortical hormone in normal rats. Our findings, here, are not in agreement with those of Dougherty and White^{10, 12} in whose hands there was an increase following adrenalectomy and a decrease on injection of cortical extract. Corey and Britton¹³ observed a fall in leucocytes in rats following adrenalectomy. The effect of turpentine injection on the total leucocytes of normal intact rats and adrenalectomized rats differed markedly. In the normal nonadrenalectomized rats there was a sharp and significant drop in leucocytes, in the adrenalectomized rats, on the contrary, no such significant fall was noticed. It seems, therefore, that the adrenal gland may be in some way connected with the peripheral leucopenia that occurs in normal rats following turpentine injection.

Both adrenalectomy and the injection of cortical extract in normal rats caused a significant rise in the number of neutrophils. These results are difficult to interpret. The turpentine injection caused a significant drop of neutrophils in normal rats but no such effect was observable in adrenalectomized rats.

In our hands, adrenalectomy did not significantly alter the number of lymphocytes. The injection of cortical hormone in normal rats, however, produced a significant drop in the number of lymphocytes and this finding is in accord with that of Dougherty and White¹⁰⁻¹². The effect of turpentine injection on the lymphocytes was the same as on neutrophils inasmuch as it produced a significant drop in the normal intact animals but none at all in adrenalectomized rats.

From the foregoing, it is clear that although the adrenal gland does not affect hypoferrremia as such, its presence may possibly be necessary for the quick recovery from hypoferrremia as well as for the delay in the onset of anemia such as occurs from turpentine injection. The adrenal gland may also be involved in the leucopenia which follows the injection of turpentine.

SUMMARY AND CONCLUSION

A series of one hundred twenty-eight albino rats was used in this study. Of these, twenty one served as normal controls, forty-five received injections of turpentine in two separate groups in doses of 0.5 and 0.1 ml, respectively, while twenty were injected with adrenal cortical extract. Of the remaining forty-two, which were all adrenalectomized, fifteen served as controls, twenty four received 0.1 ml and three 0.5 ml of turpentine. Plasma iron, hemoglobin, total and differential white cell counts were determined in these animals. Information regarding the original data has been condensed into a number of tables and the significance tested.

The following conclusions have been reached:

1 The adrenal gland has no effect on the normal level of plasma iron in rats, nor does it affect the hypoferrremia which results in these animals from turpentine injection.

2 The adrenal gland may, however, be related in some way to the quick recovery from hypoferrremia induced by the injection of turpentine.

3 The adrenal gland does not seem to have any influence on the maintenance of the normal hemoglobin level in rats, though under conditions of stress, such as turpentine injection, it may play some role in preventing a drop in the level of hemoglobin that might otherwise occur.

4 The adrenal gland is intimately concerned with the peripheral leucopenia that follows turpentine injection in normal rats. This leucopenia involved both lymphocytes and granulocytes and was not observed in adrenalectomized rats.

The guidance of Dr. George Sayers in performing the adrenalectomies is gratefully acknowledged.

IDIOPATHIC (FAMILIAL) HYPOPROTHROMBINEMIA

PAUL STICKNEY HAGEN, M D , AND CECIL JAMES WATSON, M D
MINNEAPOLIS, MINN

RHOADS and Fitz-Hugh in 1941¹ first recorded an instance of idiopathic hypoprothrombinemia as the basis for an hemorrhagic diathesis. Since then eight* additional cases have been reported.^{2, 6, 11} Hypoprothrombinemia has been noted in several individuals otherwise normal or in persons who have had only one significant bleeding episode.^{3a, 4, 6, 10} Familial hypoprothrombinemia has been demonstrated in at least four instances.^{2, 5, 6, 10}

Most of the patients thus far reported were not followed in detail over a long period of years. Some reports lack sufficient data to establish beyond doubt that the prolonged prothrombin time is due to prothrombin deficiency. Table I summarizes the cases of idiopathic hypoprothrombinemia from the literature.

The patient who formed the basis for the present study was seen repeatedly since December, 1937, on various services at the University Hospital. Besides numerous outpatient visits there were forty-seven hospital admissions. During this period a considerable mass of clinical and laboratory data was collected. The purpose of the present report is to summarize these observations, to describe recent and more detailed studies of the patient's abnormality, and to compare the information gained with that contained in the literature.

CASE REPORT

J. L., a 20 year old female domestic, first visited the University Hospital Out Patient Department in December, 1937, for study and treatment of an eight year bleeding tendency.

Past Health—Birth and neonatal periods, as well as subsequent development, were entirely normal. The patient had the usual childhood diseases, but except for the hemorrhagic tendency her past health was good.

Family History—The parents were of Swedish extraction. Their families had no blood relatives in common. The mother's paternal grandmother was said to be a bleeder. The mother had always bruised easily but had never had abnormal bleeding. No one else in the patient's ancestry was known to have a hemorrhagic tendency. The patient's siblings were normal except that the youngest, now 13 years old, had severe melena at 2 weeks of age. One brother (R) had severe rheumatic fever. Detailed studies of the immediate family will be given.

Present Illness—Nothing abnormal was observed until the child was 2 years of age when she developed a swollen, discolored, painful left knee apparently without trauma. From that time on the course was characterized by recurrent episodes of various painful joint epistaxis (up to the menarche), ecchymotic areas and deep, painful hematomas, both apparently spontaneous and obviously posttraumatic, persistent bleeding from lacerations, a few showers of petechiae especially over the buttocks, abdominal pain, and menorrhagia and metrorrhagia from the onset of menses until a recent hysterectomy. It would be difficult to say that the patient had true hemarthrosis. The joints usually were not swollen, blood was not aspirated, and no limitation of motion of any joint resulted. There never was significant hematuria.

From the Department of Medicine University of Minnesota Hospital

Received for publication April 5 1948

*Beard's case cited by Quick^{4a} is not included since recent study^{4a} showed no hypoprothrombinemia

TABLE I CASES ILLUSTRATING IDIOPATHIC HYPOPROTHROMBINEMIA

PATIENT	ALLIOTTE BY	AGE	HISTORY	FAMILY HISTORY	HEMATOLOGIC STUDIES	PROTHROMBIN TIME AND FIBRINOGEN LEVELS
1	Rhodes and Fitz Hugh	1941	♂ 18 yr Onset at 3 months with probable hemarthrosis right knee course—repeated tooth socket and gum hemorrhages, prolonged bleeding from cuts and laceration hematomas, hemarthrosis and hematuria 26 hospital admissions from 10-9 to 1940 death due to cerebral hemorrhage	None, negative for any abnormal hemorrhagic tendency	BT (Duke) ~ 20 min, often normal, CT (Larsen) 3360 min, almost always prolonged CR variable 1 G normal TT negative once positive once (~5 petechiae) but normal quantity, but qualitative effects believed present antiepilegiant behaved ruled out	Quick 70-100 sec controls ~ 20-4 sec refractory to vitamin K blood apparently had hemostatic effect
2	Giordano	1943	♂ 22 yr Onset at 5 years with frequent, spontaneous epistaxis course—recurrent epistaxis, tooth socket and gum hemorrhages, petechiae noted skin petechiae and moderate icterus	Both parents and 2 siblings hypoprothrombinemic, maternal aunt and sister known bleeders, parents and 2 siblings had positive TT, father's BT 11½ min, all had decreased serum prothrombin (0.34-5.99 gm %)	BT 7½ and 4 min, CT CR and PC normal TT positive, T 0.45 Gm % antiepilegiant study not specifically mentioned (probably not present addition of patient's plasma to control plasma did not prolong TT beyond that expected from dilution)	Smith, 9% of normal, refractory to vitamin K blood had apparent hemostatic effect, plasmin increased prothrombin in vivo
3	Lums	1943	♀ 20 yr Apparently normal individual hypoprothrombinemia detected incidentally however, a few times had strong and long lasting nosebleeds	No information given (Hemidias a report 1 brother had severe epistaxis - nephrosis, hemiparesis and hypoprothrombinemia)	CF spontaneous coagulation of recalcified blood (Larsen and Lums) 20 sec (normal 1-2 100 sec) CR and 1 G normal TT negative, 1 204 Gm % (Gram)	Larsen and Lums 30 sec, control, 18 sec refractory to vitamin K
4	Plumisa	1943	♂ 18 yr Normal individual and hypoprothrombinemia detected incidentally	No information given	CT spontaneous coagulation of recalcified blood (Larsen and Lums) 257 sec (normal 120-150 sec) 1 G normal TT negative	Larsen and Lums, 28 sec, control 18 sec refractory to vitamin K

BT Bleeding time CT clotting time CR clot retraction PC platelet count TT tourniquet test for capillary fragility I fibrinogen
PT prothrombin time (Cont'd on next page)

TABLE I—CONT'D

PATIENT	REL OUTL'D BY	YEAR	HISTORY	FAMILY HISTORY	HAEMATOLOGIC STUDIES	PROTHROMBIN TIME AND PHYSICAL TESTS
5	Quirk ^{4,6}	1943	♂, 22 yr Normal individual, hypoprothrombinemia detected incidentally	Mother and sister hypoprothrombemic (a little lower than 50%), sister has had several episodes of uterine bleeding	BT normal, CT 5.6 min, CR and PC normal, F ₂ quantitatively normal, antecogulants believed ruled out	Quick, 45% of normal, deficiency of Quirk's component B refractory to vitamin K
6	Murphy and Clark ⁷	1944	♂, 18 yr Onset at 4 years with profuse, persistent epistaxis following traumatic fracture of nose, course—recurrent epistaxis, gum hemorrhages, one episode of hematuria	Sister died at 5 years following severe, recurrent epistaxis, father slightly hypoprothrombemic (PT, Quick, 19 sec, control, 16 sec) (authors believed this was probably of no significance)	BT (Duke) 14.15 min, more frequently normal, CT, CR, and PC normal, PT negative, microscopic examination of nail bed capillaries revealed "definitely abnormal and bizarre forms", F ₂ 0.351 Gm %, "definitely suggestive evidence of some type of qualitative defect", antecogulants believed ruled out	Quick, 60-100 sec, control, 16 sec, refractory to vitamin K, blood found to have hemostatic effect
7	de Marval and Bonchis	1944	♀, 14 yr Onset of epistaxis at 8 years, course—recurrent epistaxis, then gum hemorrhages at 14 years	Parents distantly consanguineous, no bleeders known	BT normal, CT 12.40 min, CR and PC normal, TT slightly positive at times, negative at times, F ₂ 0.56 Gm %	Quick, 25-53% of normal, refractory to vitamin K
8	de Marval ¹⁰	1945	♀, 23 yr Onset at 3 years with profuse bleeding from dog bite, course—recurrent tooth socket and gum hemorrhages, hemarthrosis, menorrhagia, one normal pregnancy (spontaneous abortion), no abnormal hemorrhages at parturition	Parents were cousins, father died at 39 of an hemorrhagic disease, mother normal, but had many spontaneous abortions, four of 9 brothers died in infancy, cause unknown	BT normal, CT 10.12 min (author indicates that these levels are prolonged), CR and PC normal, TT negative	Quick, 20-25% of normal, refractory to vitamin K

6	Husserlo	1945	♂ 3 yr Onset at 3 months with prolonged bleeding from a needle puncture and bleeding from the mouth course—recurrent epistaxis, easy bruising severe hemorrhage during maxillary cyst operation at 2 years, hospitalized for severe epistaxis at 3 years	Parents distinctly consanguineous, father slightly hypoprothrombinemic (in dec 77%) brother (Patient 10) hypoprothrombinemic	BT 2.25 min CT 11 min er) 3 min 7 sec 11 min .0 sec usually prolonged CE and PC normal TT negative F 0.34 and 0.21 Gm %, anticoagulants believed ruled out	Index -1.80% to vitamin K refractory
10	Hauserslo	1945	♂, Brother of Patient 9, normal but had one episode of severe epistaxis	See Patient 9	BT normal CT (Barker) 5 min 45 sec 14 min CR and PC normal, TT negative, F quantitatively normal	Index, 53%, refractory to vitamin K
11	Lewis and Bennett 12	1947	♀, 29 yr Abrupt onset at 20 years, nasal, gum, subcutaneous, intramuscular, uterine, and urinary bleeding of 5 days' duration	Maternal aunt bruised easily	BT 45 sec CT 60 min, CR slow and incomplete, TT negative, F normal, anticoagulants believed ruled out antiprotease factor normal	Quick, 5.10 min, control, 18 sec, deficiency of Quick's component B, 1 T normal after 3 days of massive doses vitamin K, blood, and plasma
12	Quicko	1947	♂ 1 yr Onset shortly after birth with tongue and bowel hemorrhages prolonged bleeding from incisorious	Brother (Patient 13) hypoprothrombinemic, grand parents on both sides, parents, and one brother normal (sister not examined)	BT normal, CT 12.15 min, CR and 1 C normal, F quantitatively normal, anticoagulants believed ruled out	Quick, 19 sec, controls, 11.25 sec, component as say lack of neither prothrombin (component B) [nor] the labile factor but a low coagulation factor refractory to small doses of vitamin K
13	Quicko	1947	♂ 3 1/2 yr Brother of Patient 12 onset at 1 week with 3 months bleeding after circumcision course—easy bruising tooth socket hemorrhage at 5 years	See Patient 12	BT normal, CT 1.13 min CR and PC normal, F quantitatively normal, anticoagulants believed ruled out	Same as Patient 12

The patient was first admitted to the University Hospital in March, 1938, for various studies. From then until the onset of menstruation in January, 1941, there were three admissions for epistaxis or prolonged bleeding from a laceration. From the menarche until hysterectomy in September, 1945, there were thirty-seven admissions concerned primarily with the uterine bleeding. Moreover, the other symptoms mentioned recurred over this period.

After the hysterectomy there were four hospitalizations here and one elsewhere. Two were for exacerbations of ecchymoses, painful deep hematomas, and various joint aches, while three admissions were for probable intraabdominal hemorrhage. Pelvic hematomas were present on two occasions. The last admission was in March, 1947.

Various studies were made and a variety of medications was tried during these hospitalizations. However, no cause for the bleeding other than hypoprothrombinemia was demonstrated. Although vitamin K preparations, vitamin C, various hormones, and other drugs were used repeatedly, the only effective therapeutic measure was transfusion of blood or plasma.

The patient was receiving almost weekly infusions of plasma at the time of writing. This minimized but did not eliminate entirely the tendency to ecchymoses and deep hematomas. The joint aches, however, seemed to be well controlled. The last five hospitalizations occurred during periods when the plasma injections were not given with regularity.

Physical Examination—The patient was a well developed, robust appearing young woman. Examinations usually were within normal limits except for the ecchymotic areas and the deep hematomas from time to time. The hematomas usually were in the extremities, especially the lower extremities. No cardiac abnormalities were noted. The liver and spleen were not enlarged. No spider nevi were seen. A pelvic hematoma large enough to push the cervix to the introitus and palpable three fingers above the symphysis pubis was present, as mentioned. In recent years no significant abnormalities were noted about the joint even when there was aching, none had limitation of motion. Neurological examination always was normal.

Laboratory Findings—Approximately 900 laboratory results were recorded. They can be summarized as follows:

The hemoglobin and erythrocyte values were normal except during the times of severe hemorrhages. The lowest levels resulting from epistaxis and laceration were 8.8 Gm hemo-

TABLE II CEPHALIN CHOLESTEROL FLOCCULATION

globin and 3,350,000 red blood cells, while during the period of uterine bleedings the value fell as low as 4.4 Gm hemoglobin and 1,460,000 red blood cells. White blood cells, differential and platelet estimations were normal. Results of bone marrow examination Mar 27, 1940, were not remarkable. Urinalyses showed no abnormalities if catheterized specimens were examined. Neither gross nor microscopic hematuria ever was proved. Blood calcium and vitamin C levels were normal. Plasma proteins including fibrinogen repeatedly were found within normal limits. Serologic tests for syphilis were negative. The patient's blood type was A. Liver function tests consistently showed only one aberration, namely a positive cephalin cholesterol flocculation test, as detailed in Table II. Serum bilirubin levels were normal except for one elevation noted in 1941—an icterus index of 35 which was checked three

days later and found to be 4. There were no symptoms of hepatitis noted at that time or recalled by the patient. She had received 1,000 cc of blood the preceding two days but no reaction was noted. Thymol turbidity, bromsulfalein urine and fecal urobilinogen urine coproporphyrin, cholesterol, cholesterol esters, alkaline phosphatase, hippuric acid excretion, galactose tolerance and stereobilin clearance tests were all within normal limits.

The usual tests of hemostasis gave variable results. Sixty three per cent of forty nine clotting time determinations were prolonged. The clotting time was prolonged to 55 minutes twice once in 1938 and again in 1947. Approximately 40 per cent of thirteen retraction studies were abnormal. Bleeding times were prolonged in 43 per cent of forty six tests. Bleeding time recently was over 37 minutes, but usually when prolonged it was only mildly so. The cuff test was usually negative; only two tests out of thirteen were positive.

Prothrombin times were consistently elevated and in the same range over this period as illustrated by Table III.

* Selected from approximately 140 determinations on the basis of the control values which fall within Quick's 11 to 15 second range. This facilitates expression in per cent by Quick's chart.¹

Special Studies—As Quick¹ has emphasized prothrombin is estimated by a measure of its activity. The estimation is based upon certain assumptions. To prove that a delay in prothrombin time is due to prothrombin deficiency other possible causes must be excluded. Several studies were made in the present case with this objective in mind.

TABLE IV CLOTTING TIME OF RECALCIFIED PLASMA¹⁴

	LOW SPEED CENTRIFUGATION (SEC)	HIGH SPEED CENTRIFUGATION (SEC)	VENOUS CLOTTING TIME (MIN)	PROTHROMBIN TIME
Normal plasma	113	141		
Hemophilic plasma	281	433	55	17.5/18 (control)
J. L.'s plasma	74	760	51	39.7/44 (control)

1 Effect of Platelets In Quick's test the thromboplastic factor is assumed to be eliminated by the addition of an excess of thromboplastin. Nevertheless it was thought of interest to examine the effect of platelets in the present case. This was done by comparing the recalcified clotting times of low and high speed centrifugalized plasma as outlined by Quick¹⁴. The test was carried out with the results outlined in Table IV. These results reveal a behavior quite unlike that in hemophilia.

By Miss Elaine Daughenbaugh, Instructor, School of Medical Technology, University of Minnesota.

2 *Effect of Purified Prothrombin in vitro* This study was made in order to exclude the possibility of an interference with the conversion of prothrombin. This might be caused by a factor such as excessive trypsin inhibitor¹⁶ or, as recently suggested,¹⁷ by a lack of plasma accelerator factor (Ac globulin). Purified prothrombin* was prepared by the method of Seegers and associates.¹⁸ A comparison was made of the effect of progressive concentrations of this material on the prothrombin times of old plasma, dicumarolized plasma, and plasma from our patient.

TABLE V PROTHROMBIN TIME RESPONSE TO VARIOUS CONCENTRATIONS OF PURIFIED PROTHROMBIN*

TABLE VI CLOTTING TIMES OF DECALCIFIED PLASMA TREATED WITH DECREASING DILUTIONS OF THROMBIN

THROMBIN DILUTIONS	CLOTTING TIME (SEC)	
	NORMAL	J L
Full strength*	3.5	3
1:2	4	3.5
1:5	4.5	5
1:10	13.5	10
1:20	20	17
1:40	47.5	29.5
Prothrombin time	15	53.5

*Diluted solution of thrombin, topical Parke, Davis & Company, Detroit, Mich.

Purified prothrombin was added to portions of the respective plasmas to make 100 mg per cent concentrations. Then a series of dilutions with the proper untreated plasmas produced several concentrations of the added prothrombin. Quick prothrombin estimations were made on the resulting prothrombin solutions. The results are summarized in Table V. Comparison shows that our patient's plasma responded to added prothrombin as well as and in a manner similar to plasma made hypoprothrombinemic by oxidation or dicumarolization. The defect, therefore, did not seem to be an interference with prothrombin conversion.

3 *Thrombin Clotting Study* Defects in the second phase of coagulation can cause a prolongation of the prothrombin time. These may be anticoagulants.

*Supplied by Dr. Walter H. Seegers.

which inhibit the effect of thrombin, or the fibrinogen may be qualitatively defective or markedly diminished as in afibrinogenemia.¹⁹ As noted the quantity of fibrinogen in our patient was normal. Anticoagulant effect and/or fibrinogen defect may be detected by clotting decalcified plasma with increasingly dilute solutions of thrombin.¹ Table VI, summarizing the results of such a study reveals no evidence of an anticoagulant, or a defect in fibrinogen. Such abnormalities were thus not the cause of the delayed prothrombin time in our patient.

4 *Another Test for Anticoagulant* If plasma presumed to be hypoprotrombinemic, contains an anticoagulant it should prolong the prothrombin time of a control beyond that expected by dilution. However, several tests showed that J. L.'s plasma did not prolong the time of the control as much as did the addition of saline. A typical experiment resulted as follows: control plasma was 12 sec., control plus an equal amount of saline gave 16.5 sec., control plus J. L.'s plasma in equal amounts was only 13.5 sec. Again an anticoagulant could not be demonstrated in the blood.

5 *Two Stage Prothrombin Determination* To help determine whether a retarded conversion rate caused the delayed prothrombin time the procedure was done in two stages as advocated by Warner, Binkhous, and Smith.¹⁰ Prothrombin times (Quick) on control and J. L.'s plasmas were 18 and 60 respectively. The plasmas were defibrinated by the addition of thrombin solution. Part of the defibrinated control plasma was diluted 1:3. One tenth cubic centimeter of each of the three plasma samples was incubated for seventy seconds with CaCl_2 (0.1 cc of 0.25M) and thromboplastin (0.1 cc) solutions. Fibrinogen solution (0.1 cc) (Cohn's Human Fraction I used as source) was added to each and the clotting times were noted. These were 16.5, 41.5 and 58 seconds for control, diluted control, and J. L.'s plasmas, respectively. These results would indicate that our patient's deficiency was lack of prothrombin and not a delayed rate of convertibility.

Special Examinations of Plasma Proteins—(1) Electrophoretic studies of J. L.'s plasma* in 1945 revealed no significant abnormalities. (2) A cryoglobulin was found in abnormal amount. The characteristics of this protein are reported elsewhere.²⁰ It may be mentioned here however that this cryoglobulin was of unusual interest in that unlike others which have been studied it contained a carbohydrate fraction.²⁰ (3) The quality of the fibrinogen was found to be normal by thrombin clotting as detailed previously. In addition however the effect of addition of fibrinogen was tested. Bovine fibrinogen,† found to be normally active by thrombin clotting was dissolved in control and J. L.'s plasmas to make a concentration of 0.5 per cent. The prothrombin times were as follows: control 15 sec., control plus fibrinogen 15 sec., J. L. 53.5 sec., J. L. plus fibrinogen, 48 sec. This apparent 5.5 sec. decrease in the prothrombin time was not considered significant.

Component Assay—Quick⁴ has postulated that prothrombin is a complex consisting of calcium, component A, which is an oxidation labile factor and component B, which is removed by decarboxylation *in vivo* and by aluminum

* By Dr. H. L. Taylor, Laboratory of Physiological Hygiene, University of Minnesota.
† Supplied by Dr. E. C. Loomis of Parke, Davis & Company, Detroit, Mich.

hydroxide in vitro. More recently Quick⁶ speaks of component B as the "conventional prothrombin" and describes a new component A, using the term "labile factor" for the old component A. Seegers and co-workers,¹³ however, affirm that prothrombin is composed of but a single component. Deficiency of component B was found in the cases of Lewis and Bennett¹¹ and of Quick⁶. Owien¹³ has described a case which may represent a deficiency in the labile factor.⁶ Although at present the exact status of the components is not clear cut, we attempted to determine the type of component deficiency in our patient. Oxalated plasmas stored approximately one month were used as a source of plasma deficient in the labile factor. Plasma from dicumarolized patients served as a source for component B deficient plasma. The results of the experiments are recorded in Table VII. Since old plasma was more effective than dicumarolized plasma in reducing J. L.'s prothrombin time, it appears that the more important deficiency was of component B. However, the results are difficult to interpret. They may indicate that there was also some deficiency in the labile factor since, in four out of five experiments, stored plasma was not so effective as control plasma in restoring the prothrombin time of J. L.'s plasma. In three of these four experiments, however, dicumarolized plasma plus stored plasma did not result in a normal prothrombin time. Therefore, the possibility exists that there was a deficiency of some other unknown factor.

TABLE VII PROTHROMBIN COMPONENT ASSAY

	PROTHROMBIN CLOTTING TIME (SEC)				
	3/25/47	6/12/47	6/19/47	7/2/47	7/3/47

Dicumarolized plasma + stored plasma		18	14.5	21	16

Response to Vitamin K—Throughout the patient's course vitamin K and various synthetic vitamin K products in usual doses were tried without effect. The first massive dosage of synthetic vitamin K was given in 1944. Over a three day period the patient received intravenously a total of 800 mg. of hydroxide.* This was associated with a rise in prothrombin time from 70.5 to 102 seconds, the controls had a time of 17 seconds. Recently, six days after a plasma infusion, 72 mg. of menadione bisulfite were administered intravenously. The prothrombin time rose from 34 to 51.5 seconds (controls, 12 and 13 seconds) over a twenty-four hour period. This demonstrates that the patient continued to be vitamin K resistant.

*This study was made by Dr. Rudolf Marshall at that time a Fellow in Medicine, University of Minnesota Hospital.

Response to Plasma—Evidence of consistent therapeutic response to blood or plasma transfusions was recorded throughout the entire course of observation. The prothrombin times regularly decreased following such infusions. A few of the more recent examples are summarized in Table VIII. It will be noted that plasmas ten, fourteen, and thirty days old were about as effective as those only three days old. This is confirmatory evidence that the patient's main deficiency was not of the labile factor. Also this observation is of considerable practical importance since stored plasma is readily available in blood banks whereas there may be some difficulty in obtaining immediately fresh plasma or blood. Pooled dried plasma, because it has been a source of the hepatitis virus, was not given a trial in our patient.

TABLE VIII PROTHROMBIN TIME RESPONSE TO PLASMA OF VARIOUS AGES AND QUANTITIES

*Dilution of plasma with physiological saline

The bleeding and clotting times seem to respond favorably with the plasma injections. For instance, on June 19, 1947, the venous clotting time fell from 39 minutes to 15 minutes after 250 cc of plasma. The bleeding time (Duke) decreased from 9 minutes 45 seconds to 6 minutes 30 seconds. The prothrombin time diminished from 53.5 to 24 seconds (control, 15 seconds). On June 3, 1947, the ear lobe puncture continued to bleed until the plasma infusion was completed.

Capillary Examination—Microscopic observation of the capillaries of the nailbed was made.* Many so called abnormal formations were observed but not in larger proportion than often seen in normal persons. Blood flow was normal in rate and appearance. Truncation is suggested by Macfarlane¹ showed the injured capillary loop to disappear in normal fashion. Our patient's capillaries, therefore, were normal insofar as this type of examination can indicate.

Studies on Available Family Members—These studies are summarized in Table IX. Only the mother and the patient noted easy bruising. However, all members except the father showed prolongation of the prothrombin time. Although detailed assay studies were not done, addition of control plasma to plasmas from three of the family resulted in the same type of response as shown with the patient's plasma. Presumably they all had the same type of defect but in different degrees. The sister had a positive cuff test but no history of

TABLE IX PROTHROMBIN AND OTHER DATA IN THE IMMEDIATE MEMBERS OF THE FAMILY OF J. L.

bruising. However, it may be of significance that her 2 year old daughter was said to bruise easily, so far she had had no episodes of bleeding. These examinations certainly establish the familial nature of the disease in our patient.

DISCUSSION

The history and findings of a patient with idiopathic familial hypoprothrombinemia have been presented. The patient was followed in detail over a ten year period. There was a variety of studies and therapeutic attempts in order to ascertain the exact pathologic mechanism. All of the known factors other than hypoprothrombinemia which might give rise to a delay in prothrombin time were presumably excluded by the experiments detailed. There was an evident lack of the prothrombin factor which is decreased by Dicumarol (component B). There was no response to vitamin K while plasma of various ages was consistently effective. The regular occurrence of a positive cephalin flocculation test, albeit in varying intensity together with the presence of a cryoglobulin in the patient's serum tends to support the concept of a primary disturbance of protein synthesis in the liver.

The most important result of our studies was the evidence of familial incidence of the disorder. Those afflicted seemed to have the same type of deficiency. This is the fifth reported instance of familial hypoprothrombinemia. Actually the incidence is probably higher than this would indicate. Reference to Table I shows that in most cases there was a familial hemorrhagic tendency, but prothrombin estimations were not always made. Moreover, just a statement of a negative family history is not sufficient since several persons with no hemorrhagic manifestations have been found to be mildly hypoprothrombinemic. This was true in the family of J. L. Whenever the diagnosis of idiopathic hypoprothrombinemia is entertained, prothrombin determinations should be made on all available family members to help clarify the diagnosis.

SUMMARY AND CONCLUSIONS

A case of idiopathic hypoprothrombinemia followed in detail for a decade has been presented. The hemorrhagic disease in this case was characterized by epistaxis, subcutaneous hematomas, hemorrhages in proximity to various joints, menorrhagia and metrorrhagia, the latter being so severe as to require hysterectomy.

The familial character of the disease has been established in this instance. The major deficiency was of the Quick B component that affected by Dicumarol, yet vitamin K in large amounts was ineffective in shortening the prothrombin time. Purified prothrombin and human plasma, either old or fresh, were the only materials effective in this regard in vitro; the former was not used in vivo, while the latter was consistently effective in controlling the hemorrhagic tendency.

Positive cephalin flocculation and the presence of a cryoglobulin suggest that there may have been a primary disturbance of protein synthesis in the liver.

It is a pleasure to acknowledge the helpful advice and criticisms of Dr. Armand Quick during the course of this study.

OBSERVATIONS ON ALCOHOLIC FATTY LIVER THE USE OF INTERVAL NEEDLE BIOPSY AND LIVER FUNCTION TESTS

R E BUCK, MD
SALT LAKE CITY, UTAH

INTRODUCTION

DURING the past eight years, needle (trocar) biopsy of the liver has become a recognized procedure in many clinics. Its value in clinical investigation and in the diagnosis of obscure cases of liver disease is well established.

This is a report of observations on seven cases of so called alcoholic liver. Biopsies give evidence of rapid disappearance of fat following therapy in five of these cases. An attempt will be made to correlate the more important liver function tests with these changes along with the clinical features of the cases and the response to therapy.

Hoffbauer¹ recently gave a summary of the different techniques and of the indications for and dangers and advantages of needle biopsy. In a series of 1,200 cases, Sherlock² reported a mortality of 0.67 per cent. Hemorrhage is by far the most common cause of death. Other disadvantages include the failure always to secure an adequate specimen and the possibility that one shred of tissue may not represent accurately the picture of the rest of the liver. However the needle biopsy usually does offer a more representative picture than the ordinary surgical biopsy because the latter penetrates only a small distance through the capsule.

The pathogenesis of fat infiltration in the liver has been studied extensively in animals in recent years. By the use of serial needle biopsies the pathogenesis of the so called fatty liver in man should now be amenable to investigation.

Experimentally, fatty livers may be divided into two types³ those produced by an increase in the rate at which fat is supplied to the liver and those produced by a decrease in the rate at which the liver is able to dispose of fat. In the first category belongs the fatty liver produced by starvation, high fat diet and stimulation with the ketogenic fraction of the anterior lobe of the pituitary.⁴ The second group includes fatty livers resulting from poisoning with carbon tetrachloride or phosphorus, depancreatization plus insulin (dogs) and choline deficiency combined with a low protein diet. Some investigators⁵ believe that cirrhosis in man as in certain experimental animals⁷ may be the end result of extensive fat infiltration.

Incipient cirrhosis in alcoholics often is characterized by fatty infiltration and enlargement of the liver.⁸ It is in such cases (as shown below) that spontaneous remissions occur when alcohol is withdrawn and a satisfactory dietary regime is established. Treatment does not cause disappearance of the fibrosis but presumably does aid in liver cell recovery and regeneration.

From the Department of Medicine, University of Utah.
Received for publication Oct. 17, 1941.

In clinical therapeutic studies with fortified diets of various types, it has been noted that the prognosis in cirrhosis seems related to liver size.^{9, 10} Few subjects with small livers did well with any therapy, whereas those with large, easily palpable organs improved, presumably because of resorption of liver fat. Evidence is presented here that this is indeed the case.

MATERIAL AND METHODS

During the year ending in June, 1947, a total of fifty six needle liver biopsies on twenty eight patients has been attempted at the Salt Lake Veterans' Hospital and the Salt Lake County General Hospital. There were twenty two failures (due to insufficient tissue for making a microscopic diagnosis). The Roth Turkel needle was used in all instances and the technique as described by Davis and co workers³ was followed. When the liver was easily palpable, it was usually approached from below the right costal margin anteriorly. An inter costal approach in the anterior or posterior axillary line was used when the liver was not palpable.

Only the liver function tests used routinely in these selected cases are recorded in Tables I and II. These were done by generally recognized methods.^{11, 14}

Emphasis will be placed here on a selected group of seven white, male alcoholics with fatty livers. In Tables I and II a summary of the important clinical features, liver function tests, histologic observations, and treatment of these subjects is given.

Two needle biopsies were performed on each of the seven patients, the first soon after admission and the second after an interval of from three weeks to three and one half months. The first five cases summarized in the tables had a favorable outcome. Patient B N (Case 6) was committed to the state mental hospital where he expired within a month. Autopsy was not performed. Case 7 is included to contrast the course with that of the first five cases and also because the immediate cause of death was hemorrhage following a needle biopsy. One other complication occurred in the total series—a right pneumothorax. Recovery was uneventful.

CLINICAL OBSERVATIONS

All of these patients gave evidence of prolonged and severe alcoholism on admission to the hospital. The salient symptoms and signs for each are listed in Table I. They were the usual findings in varying degrees of decompensated cirrhosis and nutritional deficiency.

LABORATORY FINDINGS

The laboratory data before treatment indicated mild to moderate hepatic insufficiency. The cephalin-cholesterol flocculation test was initially positive in three of the seven cases. Of the five cases in which the thymol turbidity was measured on admission, the findings were abnormal in only two. Moderate to marked hypoalbuminemia was present in five of the seven subjects. There was bromsulfalein retention in all the patients and four had an initial mild anemia of the macrocytic type.

HISTOLOGIC OBSERVATIONS

The needle liver biopsy, done on all patients at the time of admission, showed moderate to marked diffuse fatty infiltration and from normal to moderate increase in fibrous tissue in the periportal areas. Inflammatory cells, mostly lymphocytes, were present in varying numbers at the triads. Scattered areas of degeneration of liver cord cells were observed in three patients on admission.

TABLE I CLINICAL DATA BEFORE AND AFTER TREATMENT

CASE	PATIENT	TIME INTERVAL (Wks.)	JAUNDICE	LIVER SIZE*	ASCITES	ANKLE EDEMA	OTHER MANIFESTATIONS	THERAPY
1	H K	4	++	7	+	++	Peripheral neuropathy delirium tremens	Diet† and B complex vitamins after 1000 cc Amigen and 1000 cc 10 per cent glucose daily for 10 days
			0	1	0	0	Asymptomatic gained 30 pounds	
2	W S	6	+++	10	++	0	Acutely ill, mentally obtunded, spider naevi	300 cc Parenamine in 1 liter 5 per cent glucose daily for 1 week plus multivitamins, then diet plus 300 cc Parenamine orally daily
			+-	6	0	0	Much improved, gained 18 pounds	
3	A G	4	0	4	+	+	Tremor of hands not acutely ill	House diet no other vitamins or other supplemental therapy
			0	1	0	0	Asymptomatic lost 10 pounds	
4	W O	4	+	4	0	0	Acutely ill	Diet† only no supplementary vitamins
			0	1	0	0	Asymptomatic, no change in weight	
5	H P	14	0	3	0	0	Delirium tremens, peripheral neuropathy	In hospital (8 weeks), diet † B complex vitamins plus 90 cc Protolysate per day
			0	Not palpable	0	0	Asymptomatic except neuropathy unchanged	Out patient (6 weeks) no special diet, no alcohol
6	B N	3	0	8	++	0	Korsakow's psychosis	Diet† did not eat well choline 4 Gm per day
			0	8	+	0	Unimproved, died in another hospital	
7	F W	13	0	4	0	0	None	Diet† and B complex vitamins. Improved in hospital 2 weeks, out of hospital 10 weeks did not abstain from alcohol, died following liver puncture
			+++	9	+++	+	(Third admission) Stuporous, critically ill	

*Liver size is in centimeters below the right costal margin in the midclavicular line
†Diet was composed of protein 150 Gm carbohydrate 300 Gm fat 10 Gm

Treatment consisted essentially of rest, withdrawal of alcohol a high protein, high carbohydrate, and low fat diet, and B complex vitamins

OBSERVATIONS AFTER TREATMENT

Results of treatment can be summarized as follows

- 1 Rapid clinical improvement (first five cases) such as gain in appetite strength, and weight diminution in liver size, edema and ascites and clearing of icterus in the jaundiced patients
- 2 Consistent and significant increase in serum albumin
- 3 Return of hemoglobin to normal

— Tests were not done

1+ Approximately amount seen in Fig 4 4+ illustrated by Fig 3

*Polymorphonuclears

4 Revision of the cephalin-cholesterol flocculation to negative in those cases in which it was positive

5 In contrast, only in one case out of the five in which two tests were performed was significant improvement in the thymol turbidity observed

6 Decrease in the quantity of bilirubin in the serum in the jaundiced patients with corresponding change in the bromsulphalein test. The latter returned to normal in two instances

7 Histologically, there was a consistent and marked diminution in fat in the first five subjects without marked change in periportal fibrosis and signs of inflammation. Many cells showed double nuclei. This was interpreted as evidence of regeneration.

COMMENT

It was pointed out by Hoffbauer, Evans, and Watson¹⁵ that it is not always possible to correlate closely liver function tests and anatomic findings. The same impression is gained here in cases of fatty liver. The bromsulphalein retention test and the serum albumin level seemed to be the most consistent in reflecting the clinical and histologic status before and after treatment.

It may be noted (see Table II) that the Hanger test may be negative when the liver is fatty. Thymol turbidity was variable and not markedly elevated. Similar results for these tests in cirrhosis have been noted before.^{16, 17}

Fig 1—Case 7. Specimen taken on admission showing marked fatty infiltration and slight periportal fibrosis and lymphocytic infiltration (low power hematoxylin and eosin)

Fig 2—Case 7. Specimen taken six weeks later showing marked diminution of fat with apparent increase in fibrosis and lymphocytes (van Gieson)

Fig 3—Case 3 Specimen taken on admission showing marked fatty infiltration (hematoxylin and eosin)

Fig 4—Case 3 Specimen taken four months later demonstrating marked decrease in fatty infiltration (hematoxylin and eosin)

Fig. 5.—Case 7. Specimen taken thirteen weeks before death, showing moderate ductal ectasia and early cirrhosis (van Gieson).

Fig. 6.—Specimen taken on day of death (Case 7) showing cellular necrosis and dense polymorphonuclear infiltration (van Gieson).

The finding of principal interest was the anatomic evidence of rapid diminution of fat in the first five cases. It seemed remarkable that the liver could dispose of what appeared to be an enormous amount of fat in the short time interval of four weeks (in three cases). (See Figs 1 to 4.) Presumably the processes concerned in lipid transport from the liver become effective soon after the initiation of therapy. The type of treatment seemed to make no particular difference as judged by the clinical result, function tests, and biopsy changes.

Two patients received amino acids parenterally as well as B complex vitamins and glucose intravenously until their appetites returned. Then they were given a diet of protein, 150 Gm, carbohydrate, 300 Gm, and fat, 70 grams. Patient A G (Case 3) received the house diet only (no vitamins or supplementary nourishment) and yet made a rapid recovery as judged clinically and by laboratory tests. In contrast to this, Patient B N, who was psychotic and ate poorly but received 4 Gm choline per day, showed no appreciable change in liver fat over a three-week period.

In the course of this study, one fatality occurred as a consequence of liver biopsy. Patient F W (Case 7, Tables I and II) expired three hours following the second (interval) liver puncture. This admission was his third within a year for liver disease. The patient was critically ill, with the signs and symptoms of acute liver failure. At autopsy death was shown to be due to hemorrhage from the liver biopsy wound and there was widespread necrosis and hepatitis superimposed on a fatty cirrhosis (Figs 5 and 6).

Liver puncture in this case was performed in the face of two contraindications: a prothrombin time of 50 per cent, not affected by vitamin K, and a patient too ill to cooperate. Death occurred without warning by any signs or symptoms of hemorrhage.

DISCUSSION

It appears that a good clinical result is obtainable in cases of fatty liver as long as the patient can eat, rest, and abstain from alcohol. It seems doubtful that the addition of hypotonic agents would have altered the course in the cases discussed since the rate of disappearance of abnormal amounts of lipid, in at least three of the cases, would seem to be difficult to improve upon.

The clinical syndrome of an alcoholic who enters the hospital acutely ill with jaundice, edema, ascites, and hepatomegaly is usually classified as cirrhosis of the liver. Actually all these symptoms or signs of hepatic decompensation can be produced by marked fatty infiltration and cellular damage with very little actual cirrhosis. Death may occur suddenly and at autopsy little or no trace of cirrhosis may be found.^{21, 22} Or, as reported here in the first five cases, rapid, almost complete recovery may take place. Fatty changes and the accompanying signs of hepatic insufficiency may closely simulate those of cirrhosis, yet the process is usually rapidly reversible with appropriate dietary therapy plus abstinence from alcohol.

It may be pointed out that treatment is the same regardless of the degree of cirrhosis present. The need for obtaining a picture of the histologic appearance of the liver may therefore be questioned. However, the initial pathologic

finding of only fat infiltration and the later demonstration of a relatively normal liver can be a powerful stimulus in indicating the value of an attempt at rehabilitation of the patient. The usual alcoholic relapse on discharge from the hospital might be averted if the patient and his physician had a clear picture of the changes in the liver associated with therapy and abstinence from alcohol and poor dietary habits. Resumption of former habits almost certainly would result in another episode of liver disease, whereas with abstinence, a lifetime free from liver disease can at least be hoped for.

SUMMARY AND CONCLUSIONS

Experience with fifty six attempts at needle puncture biopsy of the liver (including one pneumothorax and a death from hemorrhage) is reported.

Follow up biopsies performed in seven patients with alcoholic liver at intervals of from three weeks to three and one half months are presented, as well as simultaneous liver function studies and clinical findings.

Clinical improvement (coinciding with rapid diminution in the quantity of liver fat) was noted in five patients, and similar improvement was observed in liver function tests. In patients who could eat an adequate diet the use of supplementary lipotropic agents seemed unnecessary.

Fatty liver with a mild underlying cirrhosis may exhibit all the clinical signs of an advanced portal cirrhosis and is usually diagnosed as such. Differentiation is important in prognosis.

It is believed that if the procedure is carried out by the fewest possible operators and if due attention is given to the contraindications for the procedure liver puncture is justified in selected cases for diagnosis and prognosis. This does not imply that it should be a routine method in the clinical diagnosis of liver disease.

Serial biopsies in early cirrhosis over a period of years would add much in elucidating the natural history of the disease.

The author acknowledges the aid and advice of Dr B V Jager and Dr F D Gunn.

THE THYMOL TURBIDITY TEST IN VARIOUS DISEASES

HYMAN B STILLERMAN M D
ATLANTA, GA

THE thymol turbidity test was first described by MacLagan^{1, 2} in 1944 as an index of liver function. Since then many papers have appeared in the literature concerning its value. The exact mechanism of the test has not as yet been completely determined. The turbidity is due to the formation of a complex consisting of a globulin, phospholipid, cholesterol and thymol. MacLagan believed that the globulin was gamma globulin and that the thymol turbidity and cephalin flocculation tests had a similar mechanism. Recant and co-workers³ using electrophoretic methods, were able to show that gamma globulin was not involved in the mechanism of the thymol turbidity test while the cephalin flocculation test depended on the presence of gamma globulin. Recently Cohen and Thompson⁴ presented evidence that the protein in the complex of the positive thymol turbidity test was beta globulin. Clinically investigators^{5, 6} have felt that the basic mechanisms of the thymol turbidity test and the cephalin flocculation test were different. Kunkel and Hoagland⁷ have offered experimental evidence to show that the development of the turbidity depends on both lipids and gamma globulins in the serum. However the lipid protein complex migrates in the beta globulin fraction of the serum.

The thymol turbidity test has many advantages over other tests of liver function in current use that is stability of reagents, quantitative method of determination, short interval of time needed for performance and apparent sensitivity. It was therefore decided to evaluate this procedure by testing sera from patients with liver disease as well as various other diseases.

MATERIALS AND METHODS

The technique used for the performance of the thymol turbidity test was the modification suggested by Shank and Hoagland⁸. Sera showing 5 or more units were classed as abnormal. This was based on our own observations of the test and on the investigations of Hoagland and Shank. These workers used 4.7 units as the upper limit of normal. A cephalin flocculation test was performed on each serum at the same time that the thymol turbidity determination was done. The cephalin flocculation test was read at the end of forty eight hours and was called positive if it read 3 plus or 4 plus. In most instances total protein and formal gel determinations were also carried out. Bromsulphalein tests were done when indicated.

Although many of the patients tested were thought to have liver dysfunction a large number of tests were made on patients in whom liver disease was not thought to be present. Many patients were tested repeatedly.

From the Medical Service Grady Hospital and the Department of Medicine Emory University School of Medicine.
Received for publication Feb 4 1948

RESULTS

Tests were carried out one or more times on 567 persons. Seventy-four of these were regarded as normal controls. The results are presented in Table I, in which an attempt has been made to classify the cases. It will be noted that a positive result was obtained in 295, or 52 per cent of all persons tested.

Certain comments may be made regarding the results in the different groups.

TABLE I

GROUP	NUMBER OF CASES	NUMBER T T +	PER CENT T T +	POSITIVE THYMOL TURBIDITY TESTS	
				AVERAGE NUMBER OF UNITS	RANGE
Infectious hepatitis	36	34	94.5	23	5-50

Miscellaneous	49	28	57	7.5	6½-21
Controls	74	6	8	-	-
Total	567	295	52	-	-

Infectious Hepatitis—Series of thirty-six cases of infectious hepatitis were tested, four of these were probably cases of homologous serum jaundice. All but two of the thirty-six had a positive test, the average number of units being 23. One of the remaining cases had a negative test initially but one week later the result was positive. In the remaining case, which was typical of infectious hepatitis clinically, the thymol turbidity test remained negative throughout the hospital course. These results agree closely with those quoted in the literature.

Cirrhosis of the Liver—There were forty-eight subjects in this series and forty-six of them gave a positive thymol turbidity test. The average number of units was 20. A study of our cases revealed that the thymol turbidity test showed no essential difference between the cases of cirrhosis which occurred in alcoholics and those which occurred in nonalcoholics. Chronic hepatitis following infectious hepatitis cannot be separated from cirrhosis by the thymol turbidity test.

Of the two patients with cirrhosis with negative thymol turbidity tests on admission, one turned positive a month later while the other remained negative throughout the observation period of two weeks

Obstructive Jaundice—Five of the twelve patients in our series had a positive thymol turbidity test. Four of the five patients with positive tests were shown to have cholangitis in the presence of obstruction, and the same condition was suspected in the fifth positive case

Diseases of the Gall Bladder—This group of eleven patients included cases of acute and chronic cholecystitis as well as cholelithiasis. In six of them the thymol turbidity test was positive. It seems possible that the positive results were due to an associated cholangitis

Diseases With Widespread Liver Destruction—Eleven such cases were tested in the series, these included primary neoplastic disease of the liver, massive metastatic infiltration of the liver, and one case of massive infarction of the liver. Eight of the eleven patients had a positive thymol turbidity test

Therapeutic Malaria—Nine patients undergoing malarial fever therapy for neurosyphilis were tested. All of them had strongly positive thymol turbidity tests, with increasing values according to the duration of the fever therapy. This is in agreement with the results of other observers who have noted that other tests of liver function give evidence of liver damage^{9, 11}

Acute Lymphogranuloma Venereum—This group of twenty one cases was unusual in that the virus of lymphogranuloma venereum had been isolated in every instance¹². All but one of the patients had a positive thymol turbidity test. MacLagan in his original work included one case of lymphogranuloma venereum and that patient had a strongly positive thymol turbidity test

Rheumatoid Arthritis—Seventeen patients with acute and chronic rheumatoid arthritis were tested. Fourteen of them had a positive thymol turbidity test. The average number of units was 10. Carter and MacLagan¹³ obtained positive results in thirteen of thirty four patients with rheumatoid arthritis

Acute Rheumatic Fever—Six of eleven patients with acute rheumatic fever had weakly positive thymol turbidity reactions. The average number of units was 6.7

Heart Disease With and Without Failure—Approximately half of the patients with various forms of organic heart disease had positive thymol turbidity tests. The presence or absence of circulatory failure did not appear to influence the result. Carter and MacLagan found that ten of twenty eight cases or 36 per cent of their patients with congestive heart failure, had positive thymol turbidity tests

Chronic Lung Disease—There were twenty eight patients in this group which included such entities as bronchiectasis, empyema, pulmonary fibrosis, asthma, chronic emphysema, lung abscess and chronic pulmonary tuberculosis. Fifteen of them had a positive thymol turbidity reaction. Five of the six patients with bronchiectasis gave positive tests

Acute Infectious Diseases—Seven of sixty seven patients with acute infectious diseases were tested and 37.3 per cent showed a positive reaction. The

incidence seemed notably high in miliary tuberculosis, secondary syphilis, infectious mononucleosis, tularemia, and bacterial endocarditis. The highest value in the entire series, namely 53 thymol turbidity units, was found in the serum of a patient with miliary tuberculosis. Since infectious mononucleosis may be accompanied by a hepatitis it is not surprising to find the thymol turbidity test positive during the acute phase of this disease. MacLagan² found that six of seven patients with subacute bacterial endocarditis had a positive thymol turbidity test. Negative results were obtained in such diseases as lobar pneumonia, typhus, pharyngitis, tuberculous peritonitis, and so on.

Neoplastic Diseases—Fifteen patients were studied and seven had a positive thymol turbidity test. This group included three cases of bronchiogenic carcinoma and three of carcinoma of the colon.

Controls—Seventy-four members of the medical and nursing staffs were included in this group. Six, or 8 per cent, had positive thymol turbidity tests, ranging between 5.0 and 9.5 units. Most other workers^{1, 3, 14} have reported that the normal control subjects did not give values above 4.0 to 4.7 thymol turbidity units. Ley and co-workers¹⁵, however, determined their normal values for the thymol turbidity test statistically and concluded that the upper limit of normal was 8.7 units. Using this figure as the maximal normal level, 19 per cent of their controls had an elevated thymol turbidity test. It is of interest to note that the thymol turbidity test in 85 per cent of their controls exceeded 2 units.

COMPARISON OF THYMOL TURBIDITY TEST WITH CEPHALIN FLOCCULATION TEST

Although there is both experimental and clinical evidence that the thymol turbidity and cephalin flocculation tests depend on different factors, it was of interest to compare the two tests in our series since both are generally regarded as liver function tests. Table II shows the comparative results of the two tests in some of the larger groups of patients in the present series of cases.

TABLE II COMPARISON OF THE THYMOL TURBIDITY AND CEPHALIN FLOCCULATION TESTS

GROUP	NUMBER OF CASES	TT + CF +	TT + CF -	TT - CF +	TT - CF -
Infectious hepatitis	36	27	7	1	1
Cirrhosis	48	37	9	1	1
Obstructive jaundice	12	2	3	1	0
Lymphogranuloma venereum	21	19	1	1	-
Neurosyphilis with fever therapy	9	9	-	-	-

Infectious Hepatitis—Results of twenty-eight of the thirty-six cases agreed in both tests. There were seven tests in which the thymol turbidity was positive and the cephalin flocculation negative and one in which the cephalin flocculation was positive and the thymol turbidity negative. This is in agreement with other investigations, indicating that the thymol turbidity test is more sensitive than the cephalin flocculation test in hepatitis.^{2, 10, 17} Repeated examinations of our patients with the two tests also indicated that the thymol turbidity was a better test for following the progress of infectious hepatitis than the cephalin flocculation, since it remained positive as long as there were any symptoms of the disease. An example in a case of infectious hepatitis is illustrated in Fig. 1.

The patient was a 46 year old white woman who entered the hospital in the acute phase of infectious hepatitis. At the time of entry the thymol turbidity was 43 units and the cephalin flocculation 4 plus. The thymol turbidity fell rapidly. The patient was allowed to be out of bed thirty five days after admission before the thymol turbidity had reached a "normal" level. Within a few hours she complained of nausea and pain in the right upper quadrant. A thymol turbidity taken at this time showed a rise from 8 to 26 units. Bed rest was resumed and one day later the thymol turbidity fell to 11 units while the cephalin flocculation was 2 plus. Ninety days after admission the thymol turbidity was normal. This was forty five days after the cephalin flocculation had become negative.

Fig 1—Infectious hepatitis

This case emphasizes the usefulness of the thymol turbidity test in determining the length of convalescence in infectious hepatitis. Correlation with liver biopsy seems to indicate that the thymol turbidity test is the most accurate index of recovery from this disease.

Cirrhosis—The two tests agree in a majority of the cases. However, here also the thymol turbidity test appeared to be more sensitive than the cephalin flocculation test. There were nine cases in which the thymol turbidity was positive while the cephalin flocculation was negative. In contrast, there was only one case with a positive cephalin flocculation and a negative thymol turbidity test.

Obstructive Jaundice—In this series of only twelve cases it is not possible to draw conclusions about the relative usefulness of thymol turbidity and cephalin flocculation tests. Neither test can be relied upon to rule out this diagnosis. Their greatest usefulness seems to be in cases of jaundice with a negative thymol turbidity or cephalin flocculation. In such circumstances the chances are against the likelihood of hepatitis. However, a positive thymol turbidity or cephalin flocculation test does not rule out obstructive jaundice. It appeared that the cephalin flocculation was a slightly better diagnostic aid than the thymol turbidity test in this syndrome since the thymol turbidity test was positive in cases with cholangitis in which the cephalin flocculation test was negative.

Lymphogranuloma Venereum—It should be pointed out that the high incidence of positive results with both tests shown in this report applies to acute cases. It is probable that in chronic lymphogranuloma venereum the incidence of positive tests would not be as great. Nevertheless the possible existence of this disease must be considered when the test is employed in colored patients.

Therapeutic Malaria—Both tests were positive in all nine cases. The results here are essentially similar to those which have appeared in the literature.

TABLE III COMPARISON OF THYMOL TURBIDITY AND CEPHALIN FLOCCULATION TESTS

	NUMBER OF CASES	TT + CF +	TT + CF -	TT - CF +	TT CF
Total	567	29%	25%	6%	40%

Table III presents a comparison of the thymol turbidity and cephalin flocculation tests of our entire series. Including the control cases there were 361 cases studied. The thymol turbidity and cephalin flocculation tests agreed in 69 per cent of the cases. The thymol turbidity was positive and the cephalin flocculation negative in 25 per cent of the cases, the thymol turbidity was negative and the cephalin flocculation positive in 6 per cent of the cases. Therefore, it would seem that the thymol turbidity test is considerably more sensitive than the cephalin flocculation test.

TABLE IV COMPARISON OF THYMOL TURBIDITY AND CEPHALIN FLOCCULATION TESTS IN RARE DISEASES

DIAGNOSIS	TT	CF
Disseminated lupus erythematosus	23	-
Disseminated lupus erythematosus	16	-
Dermatomyositis	23 5	3+
General myositis	17 5	3+
Scleroderma	21 5	3+
Calcinosis universalis	12 5	-
Pemphigus	10	-
Pemphigus	-	-
Porphyria	-	-
Hypoprothrombinemia	-	-
Elephantiasis	10 5	-

Table IV shows the results of the thymol turbidity and cephalin flocculation tests in some rare diseases. There were two cases of disseminated lupus, both strongly positive with the thymol turbidity and negative with the cephalin flocculation. There was one case each of dermatomyositis, generalized myositis (possibly dermatomyositis, but with a negative skin and muscle biopsy), scleroderma and calcinosis universalis (due to dermatomyositis). Both tests were positive in three of the four cases and in the fourth case (calcinosis universalis) the cephalin flocculation was negative. One case of pemphigus gave a negative result with both tests, whereas in a second case the thymol turbidity was positive and the cephalin flocculation negative. One case of porphyria and one of idiopathic hypoprothrombinemia had negative results with both tests.

COMMENT

It appears from the results just presented that the thymol turbidity test cannot be regarded solely as a test of liver function. Positive results were frequently obtained in diseases in which there was no other evidence of liver dysfunction. Such diseases included rheumatic fever, congestive heart disease, lymphogranuloma venereum, carcinoma without liver involvement, and so on. The thymol turbidity test should be looked upon only as a measure of abnormal serum protein pattern, not necessarily related to liver function. It is conceivable that many conditions other than liver disease might occasion a change in the pattern of the serum proteins. Evidence in favor of this hypothesis is offered by the number of positive thymol turbidity tests in the control series of apparently normal healthy young men and women of the professional staffs.

In cases of liver dysfunction, the thymol turbidity test is a rather sensitive test in such diseases as infectious hepatitis, cirrhosis, Weil's disease, malaria, and so forth. While it is a great aid in diagnosis of these conditions, it can be used to follow the progress only of infectious hepatitis and probably Weil's disease. Labby and co-workers¹⁸ have shown that neither the thymol turbidity nor the cephalin flocculation test is of value in following the progress of cases of cirrhosis. This is unfortunate since the thymol turbidity test is a quantitative test and can be performed easily.

There are certain features of rheumatoid arthritis that is palmar erythema, the remission of symptoms with the onset of jaundice, and the positive liver function studies,¹⁹ which seem to indicate dysfunction in the liver in rheumatoid arthritis. The high percentage of positive thymol turbidity tests in this disease adds another link in the circumstantial evidence of such a relationship.

It has long been recognized that lymphogranuloma venereum is a generalized disease. The incidence of this disease is rather high among Negroes. Beeson and Miller²⁰ have shown that many Negroes have abnormal serum protein reactions as evidenced by positive formol gel reactions. They postulated the possibility that these two findings were related. The high incidence of positive thymol turbidity and cephalin flocculation tests in lymphogranuloma venereum tends to confirm this hypothesis.

SUMMARY

The sera of 567 individuals were studied in order to evaluate the thymol turbidity test. The results indicate that the thymol turbidity test should not be regarded as a specific test of liver function. It appears to depend upon abnormal protein patterns which may or may not reflect liver disease. Many conditions in which all other tests of liver function are normal may have a positive thymol turbidity test.

The test is of greatest value in following the progress of cases of infectious hepatitis.

Both thymol turbidity and cephalin flocculation are frequently positive in lymphogranuloma venereum and rheumatoid arthritis, thus necessitating cautious evaluation of the tests in the presence of these diseases.

Negative thymol turbidity and cephalin flocculation tests are helpful in the differential diagnosis between obstructive jaundice and hepatogenous jaundice. Positive results, however, should not be relied upon to rule out the possibility of obstructive jaundice. The thymol turbidity is frequently positive if obstruction is complicated by cholangitis.

ETHYLENE GLYCOL POISONING

A CLINICAL AND PATHOLOGIC STUDY OF THREE CASES

PAUL O HAGEMANN, M.D., ST LOUIS, MO., AND THOMAS R
CHIFFELLI, M.D. NEW HAVEN, CONN

CONFUSION in the layman's mind over the varying composition of anti freeze solutions has led to the accidental poisoning of an increasing number of individuals. Under these circumstances ethylene glycol solutions (for example, Prestone) have been ingested with serious results in each instance. Such accidents might be avoided to some extent if containers of ethylene glycol solutions were more conspicuously labeled Poison.

Ethylene glycol ($\text{HOCH}_2\text{CH}_2\text{OH}$) is a colorless odorless liquid which has a characteristic pleasant bittersweet flavor. In vivo ethylene glycol is oxidized to oxalic acid and then to glycolic acid. Its toxicity has been studied rather extensively experimentally by a number of workers.

Experimental Data—Page¹ studied the effects of ethylene glycol in dogs, rabbits, and rats, and in fatal poisoning he found hemolysis of blood, bloody urine, and distended urinary bladders. Comparing the toxicities of ethylene glycol, propylene glycol, and diethylene glycol, Holec found that animals died twice as fast with ethylene glycol. Laug and co-workers² describe weakness, lack of coordination, coma, and death in animals fed ethylene glycol. Pathologic studies revealed hydropic degeneration of convoluted tubules and focal necrosis of the liver. In addition, pulmonary congestion and hemorrhage were noted as well as hemorrhages in the stomach. They found the LD_{50} of ethylene glycol to be about half that of diethylene glycol in most animals. These results were confirmed by Smyth, Seaton, and Fischer.⁴

Kesten and co-workers⁵ described experimental renal lesions with calcium oxalate deposits and high blood nonprotein nitrogen values following ethylene glycol administration. Similar lesions were observed by Morris and associates⁶ in rats, including the formation of calcium oxalate bladder stones.

Wiley and co-workers⁷ recognized the conversion of ethylene glycol to oxalic acid in experimental animals but did not feel that such conversion occurred in amounts sufficient to explain its toxicity. Similar data are presented by Muhns and co-workers⁸ who found crystalline deposits only in chronic toxicity experiments. Administration of sodium oxalate in appropriate amounts did not cause death in experimental animals. They found no hydropic degeneration of kidney tubules and felt that animals died of extrarenal causes. Wiley⁷ described lymphocytic meningeal reactions in experimental animals following ethylene glycol administration. Newman and associates⁹ perfused livers with ethylene glycol and found oxygen consumption depressed and lactic acid formation increased.

From the Department of Medicine, Washington University School of Medicine and the Barnes Hospital, St. Louis, Mo., and the Department of Pathology, Yale University, New Haven, Conn.

Experimental evidence thus suggests that ethylene glycol acts as a depressant to the central nervous system and produces lesions in the kidney, liver, and lung

Clinical Data—Bachem (1917)¹⁰ drank ethylene glycol and observed an increase in excretion of oxalic acid in the urine. In 1927 Page¹ drank 15 cc diluted without effect.

In 1930 Hausen¹¹ reported two cases with recovery. Decapsulation of the kidney was performed in one instance. In the same year Bickke¹² reported two cases successfully treated with unilateral renal decapsulation. Three additional cases have been reported in brief^{13, 14}

In 1943 Boemke¹⁵ reported four fatal cases with necropsy findings. Two of his patients exhibited hyperemia of the brain and leptomeninges, small ring hemorrhages in the brain stem, and perivascular cell infiltrates in the gray and white matter of the cerebrum. Sections of the kidneys revealed dilated tubules with fat droplets in the epithelium. The lumen of tubules contained hyaline material, crystals, and red blood cells. Boemke attributed changes in the brain to previous typhus infections.

A clinical and pathologic report of eighteen fatal cases was published by Pons and Custer¹⁶. The clinical description of these cases emphasized the predominance of the neurological manifestations, that is, coma, convulsions, and so on. The urine contained oxalate crystals in each recorded instance. All tissues were congested. Calcium oxalate crystals were seen in all kidney sections and in occasional brain sections. The authors emphasized the inflammatory reaction seen perivascularly in the brain and diffusely in the meninges. In some instances hemorrhage accompanied this infiltration. Degenerative changes in cells of the brain were also found. These authors felt the lesions in the central nervous system explained the fatal outcome in acute severe ethylene glycol poisoning.

Another case with clinical and pathologic findings has been reported in detail by Milles¹⁷. This patient was euphoric and later depressed, he developed hypertension and fever and died twenty-two hours following the ingestion of ethylene glycol. Autopsy revealed pulmonary edema, injection of pial vessels, and swollen and vacuolated liver cells. The glomerular capillaries were distended and tubular epithelium was swollen. Crystals were seen in the tubules. The acute course was attributed to oxalate poisoning, and several therapeutic suggestions were given with this in mind.

CASE PRESENTATIONS

The three patients herein presented were admitted to the station hospital at Los Alamos, N. M., following a drinking bout during which one of the victims induced his friends to share his "wine". The quantities consumed could not be estimated with any accuracy. The material was consumed from three to five hours prior to admission.

CASE 1—A. B., a 36 year old Spanish American, was admitted to the hospital in coma about three hours after he had ingested the "green wine."

Physical Examination The temperature was 101 F, pulse rate 128, and respiratory rate, 44. Slight cyanosis was present. Greenish froth exuded from the nose and mouth. The pupils reacted to light. Heart, lungs and abdomen were negative. Blood pressure was 100/90. Reflexes were absent and extremities were flaccid.

Laboratory Examination The red blood count was 5,350,000 hemoglobin content, 14.5 Gm. per 100 c.c., and white blood count 32,300. Differential white cell count was as follows: neutrophils, 91 per cent, stab forms, 4 per cent, metamyelocytes, 1 per cent, lymphocytes, 1 per cent, monocytes, 3 per cent. Urinalysis showed a specific gravity of 1.009, acid reaction, a trace of albumin, 2 plus sugar (glucose iv), numerous red blood cells and a few crystals resembling hippuric acid. Spinal fluid was slightly cloudy and contained 214 white blood cells per cubic millimeter, globulin was 4 plus and total protein was 170 mg per cent. Blood nonprotein nitrogen was 81 mg per cent and carbon dioxide combining power was 7.5 volumes per cent.

Course The stomach was immediately lavaged with 4 per cent solution of sodium bicarbonate, and 500 c.c. of this solution were left in the stomach. One liter of 10 per cent glucose in distilled water and 1 liter of one-sixth molar sodium lactate in normal saline were given intravenously. Oxygen was given by nasal catheter. The patient remained unconscious, the pulse became very rapid and weak and the respirations rapid, deep and labored. The nasal tube was inserted twelve hours after admission and 2 Gm. of sodium bicarbonate were given by tube each hour for six doses. A series of generalized convulsions began at this time and the blood pressure fell to 60/20. Magnesium sulfate was given intramuscularly in an effort to control convulsions. An additional 2 liters of one-sixth molar sodium lactate were given. The patient expired twenty hours after admission.

CASE 2—M S, a 27 year old Spanish American, was found unconscious in a furnace room, where he evidently had collapsed while attempting to carry out his duties as a fireman. Approximately three hours previously he was reported to have consumed some green liquid with the first patient.

Physical Examination Temperature was 98 F, pulse rate, 90, respiratory rate, 32, and blood pressure 140/90. The patient was comatose but reacted slightly to painful stimuli. Pupils were dilated but reacted to light. Heart, lungs and abdomen were not notable. The limbs were flaccid and reflexes were absent.

Laboratory Examination Blood count revealed 5,820,000 red blood cells, 18.8 Gm hemoglobin, and 37,200 white blood cells. The differential white cell count was as follows: neutrophils 85 per cent, stab forms, 4 per cent, lymphocytes 1 per cent, monocytes 10 per cent. Urinalysis showed a specific gravity of 1.009, acid reaction, a trace of albumin and sugar, 3 to 5 red blood cells per high power field, and numerous crystals resembling hippuric acid. The spinal fluid was slightly cloudy and contained 62 white blood cells per cubic millimeter. Globulin was 4 plus and total protein, 170 mg per cent. Blood nonprotein nitrogen was 60 mg per cent, and carbon dioxide combining power, 7.5 volumes per cent.

Course Therapeutic efforts were identical with those described in Case 1, namely gastric lavage, liberal administration of fluids, alkali, and oxygen. The patient remained comatose, the pulse rate rose to 136 and the respiratory rate to 36. Breathing was deep, labored and rapid. Blood pressure rose to 190/105. Generalized convulsions began fifteen hours after admission, following which the patient failed rapidly with a fall in blood pressure to 70/40. The patient expired seventeen hours after admission.

CASE 3—P B, a 53 year old Spanish American, was brought to the hospital for observation because he had consumed one drink of the same liquid. The patient was at work when contacted and except for appearing slightly intoxicated and unsteady was in satisfactory condition. In addition to the drink, which was consumed eleven hours before admission, the patient had had several bottles of beer and several "shots" of whiskey during the day. There had been no nausea, vomiting or other untoward symptoms.

Physical Examination The rectal temperature was 98° F, pulse rate, 130, and respiratory rate, 24. The patient was well oriented, cooperative, and did not appear ill. Conjunctival vessels were injected. The pupils were small and reaction to light was questionable. No other abnormalities were noted.

Laboratory Examination Red blood cell count was 4,980,000, hemoglobin content 12.4 Gm per 100 cc, white blood cell count, 40,000. Differential white cell count revealed neutrophils, 89 per cent, stab forms, 10 per cent, lymphocytes, 3 per cent, and monocytes, 5 per cent. Urinalysis showed a specific gravity of 1.009, acid reaction, no albumin or sugar, there were numerous red blood cells and crystals resembling hippuric acid. Stomach content showed no free hydrochloric acid and 4 plus occult blood. Spinal fluid contained 39 white blood cells per cubic millimeter, 4 plus globulin, and total proteins of 124 mg per cent. Blood nonprotein nitrogen was 59 mg per cent and carbon dioxide combining power, 3 volumes per cent.

Course Three hours after admission the patient became restless and lapsed into coma. Oxygen was administered and 1 liter of one sixth molar sodium lactate was given intravenously. Respirations were shallow and rapid. Blood pressure was 195/80. Nine hours after admission respirations became very labored and shortly thereafter the patient became cyanotic and respirations ceased. The patient was revived with artificial respiration, adrenalin, and Coramine, but remained comatose. The pulse remained rapid and weak and respirations were deep and labored. A second liter of one sixth molar sodium lactate was given. Sodium bicarbonate (2 Gm) was given by nasal tube every two hours for four doses. The patient expired seventeen hours after admission.

Autopsy Findings —

Gross Pathology The external appearance in all three instances was not remarkable. Livor mortis and a moderate degree of rigor mortis were present. Following the primary incision, in each case the urinary bladder was found to be greatly distended to the level of the umbilicus and filled with clear, pale urine. In all three, the gross appearance of the organs was nearly identical save for the presence of active tuberculous pulmonary lesions in Cases 1 and 2.

All organs showed moderate to severe engorgement of vessels. Although the peritoneal surfaces were not remarkable, the pleural surfaces, both visceral and parietal, were studded with petechial hemorrhages, hemorrhagic streaks, and several large subpleural hematomas. The lungs were markedly congested, more so in the posterior dependent portions, and on cross section revealed multiple small hemorrhagic areas scattered throughout the parenchyma, varying in number in each case. The pericardium was of normal appearance, but the epicardial surface was streaked with large, recent hemorrhages sometimes reaching the proportions of hematomas. These hemorrhages were found principally along the coronary vessels and their branches and over the auricles. In one case tiny hemorrhages were observed in the adventitia of the superior vena cava, near the heart, in another, similar petechial hemorrhages were seen in the adventitia of the ascending aorta. The relative size of the hearts was not remarkable and no cardiac dilatation was noted. Grossly the myocardium was not significantly altered, but in one case small hemorrhages were seen in the endocardium.

The stomachs and intestines were not remarkable, except for congestion and occasional small mucosal hemorrhages. The mucosa of the esophagus, in each case, was smoky-gray in color with one or two small points of epithelial sloughing. The livers were not enlarged, they were deep reddish brown in color with

Fig 1—Section of lung through hemorrhagic area showing deposition of fibrin like material lining the alveolar walls and extensive extravasation of red cells into the alveolar spaces (X100)

Fig 2—Section of superficial myocardium showing extensive recent extravasation of blood (X100)

Fig 3—Liver showing marked perisinusoidal edema containing albuminous deposits ($\times 80$)

Fig 4—Liver showing marked fatty infiltration ($\times 100$)

distinct markings, but showed no other significant changes. The kidneys were of normal size and markedly congested, and in one or a few petechial hemorrhages were noted under the capsule. Small hemorrhages were seen in the pelvic lining of all and in the bladder mucosa of two.

The brain, in each case, showed marked vascular engorgement with scattered petechial hemorrhages over the surfaces and within the sulci. The cerebrospinal fluid was grossly clear and the ventricles were not dilated. Coronal sections at 10 cm intervals showed only congested and dilated vessels in two instances, and in a third, a few scattered petechial hemorrhages in the white matter. In two instances, recent hemorrhage was present in the mastoid cells.

Histopathology The microscopic pictures of all three were relatively similar to one another except for variations in degree which will be mentioned. No space will be given to description of the tuberculous lesions of the lungs. Tissue sections from the lungs revealed moderate alveolar distension, emphysema and variable degrees of capillary congestion especially in the dependent portions of the lungs. In all lobes many small and large areas of recent hemorrhage within the parenchyma and subpleurally were noted. The alveolar walls intermittently presented a uniform pink staining material having a fibrinoid appearance (Fig 1). This material formed heavy deposits lining the alveolar walls, sometimes sloughing off into the alveolar spaces. Some of the capillary endothelial cells were swollen and in many places actually appeared degenerate and became contiguous with the fibrin like deposits. In Cases 2 and 3 congestion and hemorrhage were marked but the fibrin like deposits were seen only in scattered places.

Sections of the myocardium in each case showed many large recent extravasations of red cells under the epicardial membrane and scattered throughout the myocardium between the muscle fiber bundles (Fig 2). The vessels again were markedly dilated and very occasionally hyaline like degeneration of the capillary wall similar in character to that of the pulmonary capillaries was found. There were areas in which degenerative changes of the myocardial fibers had taken place consisting of interstitial edema swelling of the fibers and loss of cross striations. A fat stain (sudan II) revealed a diffuse deposit of finely granular lipid substance in the muscle fibers.

Although grossly the livers showed no specific changes the sections evinced a fairly well preserved architecture with the presence of wide zones of edema between the liver cord cells and the venous sinusoids. In most instances, these wide edematous spaces contained variable quantities of amorphous albuminous material (Fig 3). The liver cells although well preserved were filled with many large vacuoles. Sudan II staining revealed numerous fat droplets in the cytoplasm of the liver cells. This was especially striking centrally, but affected about three fourths of the lobule (Fig 4). Sections of the spleen showed foci of hemorrhage and diffuse congestion.

Sections of the esophagus revealed rather well preserved epithelium which was raised from its base and interrupted in two or three places. An occasional nucleus appeared pyknotic but for the most part the cells were normal and stained well. The immediate subepithelial layers were intensely congested with

Fig 5—Tufted crystalline deposits in renal tubule Note the well preserved epithelial lining ($\times 970$)

a few small hemorrhages. The vessels, however, did not show any evidence of degeneration or focal necrosis. Sections of the stomach and small and large intestine were not especially remarkable. There was marked capillary dilatation, engorgement, and edema of the lamina propria. Occasionally small hemorrhages were seen.

The kidneys showed the most striking distention of capillaries, arterioles, and venules alike. In many instances, there were small amounts of blood extravasated outside the vessel walls. The glomeruli were large but without proliferation of epithelium or endothelium; here, too, there was marked distention of the capillary loops forming lakes of blood which could be interpreted as true stasis. There was no evidence of capillary degeneration nor of hyaline necrotic mural changes such as were seen in the lung. Although the lining epithelium was well preserved, approximately two thirds of the renal tubules contained large grayish crystals, many appearing as shocks of wheat with a central binding similar to sulfathiazole crystals but smaller (Fig 5), others showed irregular plate-like appearance similar to uric acid crystals. Positive identification of these crystals was not made.

Numerous sections were taken from various portions of the brain (the frontal and occipital lobes, the internal capsule, cerebellum and dentate nucleus, pons, medulla, and olive) and spinal cord. The changes in nearly all

Fig 6—Meninges. The thickening of the pia arachnoid is chiefly perivascular consisting of predominantly neutrophilic leucocytes moderate numbers of lymphocytes and pale monocytes and extravasated red cells (X100)

Fig —Small cerebral vessels showing perivascular edema and intensive diapedesis of leucocytes and red cells (X430)

sections included simple vascular congestion, the diapedesis of leucocytes into the perivascular spaces, the extravasation of red cells, and frank exudative meningo-encephalitis (Fig 6). Some vessels showed only moderate numbers of leucocytes infiltrating through the vessel walls and filling the perivascular space. This infiltrate consisted chiefly of neutrophiles with varying numbers of lymphocytes and palely stained mononuclear cells. Other vessels showed perivascular infiltrations of equal numbers of leucocytes and red cells (Fig 7). Occasionally, however, only red cells were seen about the vessels, sometimes in ring form. In only one of these cases (Case 1) was the pia-arachnoid found to be universally infiltrated with extravasated blood, serum, and leucocytes, principally neutrophiles. In this case, the superficial vessels of the parenchyma also showed a marked perivascular cuffing with neutrophiles, lymphocytes, and occasional monocytes. In the remaining two cases only few focal areas of meningeal infiltration were seen, the principal changes being congestion, edema, and focal hemorrhages. These vascular changes were found in all sections of the brain stem and in the spinal cord as well. Some of the small vessels were filled with hemolyzed blood cells. Curiously enough, in one section of the internal capsule (Case 2) several of the small capillaries exhibited crystalline tufts exactly similar to those found in the renal tubules. With toluidine blue stain, in most instances, the ganglion cells appeared to be well preserved and arranged perpendicularly to the brain surface. However, in each case there were scattered focal areas of derangement of these large cells which stained deeply and appeared somewhat pyknotic. Occasionally chromatolysis as well as satellitosis with oligodendroglia was observed. Early chromatolytic changes of the ganglion cells of the spinal cord were also seen. Myelin stains showed no abnormality, and modified Spielmeyer's stain of peripheral nerves showed no evidence of demyelination of nerve fibers.

Sections of thoracic and abdominal lymph nodes, aorta, bone marrow, prostate, testis, adrenals, thyroid, pituitary, and peripheral nerves showed no significant alterations.

TABLE I ETHYLENE GLYCOL CONTENT OF TISSUES AND URINE
(EXPRESSED IN MILLIGRAMS PER CENT)

	CASE 1	CASE 2	CASE 3
Brain	500	450	400
Liver	133	100	662
Kidney	410	440	500
Urine	1650	1000	1000

Chemical Laboratory Analysis Portions of brain, liver, and kidney were analyzed for presence or absence of common poisons and ethylene glycol. Equal samples in each case were submitted as well as samples of the urine and gastric contents. The post-mortem gastric contents were negative. The tissue sections were entirely negative for the common volatile poisons, alkaloids, and heavy metals. Special procedures were instituted for the qualitative and quantitative assay of ethylene glycol and the results are incorporated in Table I.

Technique employed for detection of ethylene glycol in body tissues and urine

Brain, Liver, and Kidney Twenty five grams of tissue were chopped finely with scissors and transferred to a 500 ml side arm distilling flask. 20 to 25 cc distilled water were added. Steam distillation was carried out until 30 cc of distillate were obtained. The residue was centrifuged and the total volume measured and made up to 50 cubic centimeters. Two cubic centimeters of $2/3$ N sulfuric acid and 2 cc 10 per cent sodium tungstate were added to 16 cc of the supernatant fluid. To 5 cc of the filtrate were added 25 cc 2 per cent potassium permanganate and 0.8 cc concentrated sulfuric acid. After standing five minutes, 0.5 cc 10 per cent oxalic acid and 0.6 cc concentrated sulfuric acid were added. After the solutions became colorless 5 cc Schiff's reagent were added. After fifteen minutes the unknowns were compared with standards that were prepared simultaneously. Normal body tissues were employed as controls. These were uniformly negative for ethylene glycol.

Urine Urine was tested in a similar manner. One cubic centimeter urine plus 4 cc distilled water were used instead of the 5 cc filtrate employed in tissue analysis. Normal controls were again negative.

Formaldehyde was detected in urine by adding 1 cc Schiff's reagent to 3 cc distilled water and 1 cc urine. The pink colors were compared with standards prepared simultaneously.

The urine also was found to contain small quantities of formaldehyde (presumably an oxidation by product) in the following amounts:

Case 1	40 mg per cent
Case 2	52 mg per cent
Case 3	44 mg per cent

The heaviest concentrations of the specific agent in the brain and in the urine were found in Case 1. Correspondingly, the tissue sections showed the most dominant lesions histologically.

DISCUSSION

The bottle from which these patients drank an unknown quantity was shown by analysis to contain a 40 per cent solution of ethylene glycol. Tests for methyl alcohol on the same liquid were negative.

The picture presented by all three patients was strikingly similar being characterized by coma, acidosis, hypertension, convulsions, and death. The widespread toxic reaction was evidenced clinically by the extreme leucocytosis, albuminuria, microscopic hematuria, nitrogen retention, lowered carbon dioxide combining power and spinal fluid changes. The therapeutic efforts had no apparent beneficial effect.

The pathogenesis of ethylene glycol toxicity in man is not clearly understood. Pons and Custer¹⁰ attributed the main effect to a chemical meningitis and Milles¹⁷ to ovalate poisoning. The evidence presented in these three cases seems to indicate widespread capillary damage. This is assumed to be the primary lesion. Widespread hemorrhages result as seen in pleura, lung, heart, pericardium, kidney, and brain. In all three, the brains and vessels were congested with perivascular infiltration of leucocytes and red blood cells. In Case 1 the changes in the meninges and brain were more diffuse and well developed, suggesting a chemical meningoencephalitis. The edema and fat infiltration seen in the liver were striking and presumably represent a direct toxic effect. Crystals (presumably calcium oxalate) seen in kidney tubules and in the brain were considered a characteristic but unimportant finding.

The demonstration of ethylene glycol in body tissues and in post mortem urine serves to demonstrate its wide distribution corresponding with the diffuse pathologic lesions. The high concentration of the chemical in the urine re-emphasizes that the principal path of excretion is via the kidney.

Specific therapeutic measures do not seem to be at hand.

THE ACTION OF PILOCARPINE ON THE LUNGS IN NORMAL AND ASTHMATIC SUBJECTS

JOHN J. CURRY, M.D., AND SAMUEL E. LEARD, M.D.
BOSTON, MASS.

THE reaction of the tracheobronchial tree to histamine and acetyl-beta methyleholine (Meeholyl chloride) in normal and asthmatic subjects has been described by one of us (J. J. C.) in previous reports.^{1,2} While it was shown that in the latter subjects the parenteral injection of either histamine or Meeholyl chloride induced asthma-like attacks, with reduction in the vital capacity, it appeared that the respiratory tract was more reactive to Meeholyl chloride than to histamine in many of the cases. In view of the implication of these findings with regard to the etiology and possibly the therapy of spontaneous asthma, it was felt that further study of the role of the parasympathetic nervous system in bronchial asthma was warranted. The present communication deals with the action of a parasympathomimetic drug, pilocarpine, on the tracheobronchial tree in normal and asthmatic subjects. Comparison of the respiratory reaction after pilocarpine with that following Meeholyl chloride, and in some instances Prostigmine, is also made in an attempt to furnish further information on the pharmacodynamic action of pilocarpine.

Few studies on pilocarpine have been made in man except those dealing with the action of the drug on the sweat glands. This substance acts on cells innervated by postganglionic cholinergic fibers and exhibits most of the muscarinic but not the meotinic properties of acetylcholine.⁴ It is not clear whether or not pilocarpine produces a discharge of epinephrine from the adrenal gland for there are conflicting reports.⁵⁻¹⁰ The occurrence of such a discharge would influence our studies since epinephrine causes pronounced bronchodilation and counteracts the action of some parasympathomimetic drugs on the respiratory tract in asthmatic subjects.¹¹ In 1921 Alexander and Piddock¹² gave 3 mg. of pilocarpine subcutaneously to twenty asthmatic patients and in ten, asthma-like attacks were precipitated as a result of the injection.

METHOD AND MATERIALS

Pilocarpine hydrochloride was administered intramuscularly or intravenously in doses of 1 to 5 mg. to a group of normal subjects and to a group of asthmatic patients. The reaction of the respiratory tract was measured chiefly by recording the vital capacity on a rapidly moving drum according to a method previously described.¹ The first group was composed of ten subjects who had no personal or family history of allergy and no signs or symptoms of allergic disease or bronchitis. In the second group were seventeen ambulatory patients with bronchial asthma. No attempt was made to classify the type of asthma but the majority of patients were young adults subject to attacks at any time during the year. For

Received for publication Jan. 26, 1935.

purposes of comparison they were divided into three groups, depending chiefly on the number and severity of the attacks. The majority of these subjects had been studied previously, had performed numerous vital capacity tests, and were well trained and very cooperative.

Pilocarpine hydrochloride* was dissolved in sterile isotonic saline to a concentration of 10 mg per milliliter and placed in a sterile rubber capped bottle. The solution was replaced at monthly intervals and stored in a refrigerator when not in use.

RESULTS AND COMMENT

Normal Subjects—In the group of ten normal subjects the intravenous injection of 2 to 5 mg of pilocarpine produced no significant reduction in the vital capacity (Table I). Similar results were obtained after 6 mg doses of Mecholyl chloride given intramuscularly in a previous study.³ There was no subjective sensation of tightness in the chest after pilocarpine, however, as

noted following the administration of Mecholyl chloride. Coughing was experienced occasionally and salivation persisted for a longer period of time after pilocarpine than after Mecholyl chloride. The increase in vital capacity after pilocarpine in some of the subjects perhaps might have been due to the fact that they were not so well trained as the asthmatic group. However, the control vital capacities were uniform. The sweating response in this group following comparable doses of pilocarpine was apparently uniform as judged by clinical observation. The heart rate was consistently elevated. In these respects the findings were similar to those obtained with Mecholyl.

Asthmatic Subjects—All of the seventeen asthmatic patients suffered a reduction in vital capacity after the administration of 1 to 4 mg of pilocarpine intramuscularly or intravenously and in many instances the reaction was severe (Table II). However, one subject (J B), who had mild asthma, had a reduction of only 2 per cent with 4 mg by vein, and another subject (R B), who had

1+ Asthma patients with only a past history of asthma or with one or two attacks a year
 + asthma patients with asthmatic paroxysms one or two times a month 3+ asthma patients with one or two attacks or more a week

daily asthmatic paroxysms, had a reduction in vital capacity of only 1 per cent with an intravenous dose of 2 milligrams. The latter subject also experienced a reduction in vital capacity of only 3 per cent after histamine but in contrast the intramuscular administration of 2 mg of Mecholyl chloride was followed by a decrease in vital capacity of 48 per cent from the resting level of 2,404 milliliters. All the asthmatic patients given up to 6 mg of Mecholyl chloride in a previous study also reacted with a reduction in vital capacity. The intensity of the asthma like attack and the degree of reduction in vital capacity were greater after Mecholyl chloride than after pilocarpine with the doses used in these studies.

The degree of flushing, salivation, and sweating in the asthmatic patient did not appear to differ from the responses seen in the normal subjects after comparable doses of pilocarpine. In this respect our findings differed from those of Alexander and Paddock,¹² who concluded that flushing, salivation, and sweating were somewhat more pronounced in asthmatic patients than in normal subjects with similar doses of pilocarpine. The reaction pattern of the tracheobronchial tree, as determined by repeated vital capacity tests at intervals after the injection of pilocarpine, was variable, in contrast to the reaction after histamine and Meeholy.

Intramuscular Injection—After the intramuscular injection of 3 to 4 mg of pilocarpine in the asthmatic patients, flushing, salivation, and mild sweating appeared within a few minutes, but the maximum reduction in vital capacity did not occur for from six to twenty-five minutes. The following case illustrates the reaction of Subject F G (Fig 1) to the intramuscular injection of 3 mg

Fig 1—Comparative effect on the vital capacity of pilocarpine given intravenously and intramuscularly in Subject F G. Horizontal line represents time in minutes after the injection. Interrupted vertical line indicates change from one- to five minute time intervals. The unshaded box on the left shows the control range of vital capacity determinations.

of pilocarpine. In the first six minutes after the injection, despite the subjective sensation of tightness in the chest, there was no reduction in the vital capacity. However, fifteen minutes following the pilocarpine administration there was a reduction of 543 ml in the vital capacity and wheezing appeared. The reaction to the drug had disappeared in thirty minutes and the vital capacity was near the resting level. The delay in appearance of tightness in the chest and the more prolonged delay in reduction in the vital capacity following the injection of pilocarpine clearly is not due to slow absorption, since other systemic effects such as salivation and flushing are manifest within a few minutes after administration of the drug. In this respect the reaction of the

tracheobronchial tree after intramuscular pilocarpine differs from the reaction due to intramuscular Mecholyl chloride. After the latter a notable reduction in vital capacity is present in two minutes and the maximal effect is present in four to six minutes. In many cases the vital capacity may have returned nearly to the resting level fifteen minutes after the intramuscular administration of the drug. It is interesting to note that the reduction in vital capacity in asthmatic subjects due to intramuscular or intravenous Prostigmine methylsulfate¹³ is similarly delayed in onset and resembles the tracheobronchial reaction due to intramuscular pilocarpine. As will be shown later a second and delayed reduction in vital capacity was also found in many of our subjects after the intravenous administration of pilocarpine. The precise explanation for this delay of tracheobronchial reaction to pilocarpine is not clear. It is possible that the liberation of epinephrine as a result of the injection may in some way manifest a temporary protecting action against the tracheobronchial effect of the drug. It will be shown subsequently that epinephrine may afford protection against the effect of pilocarpine in the lungs without affecting the flushing, salivation, and sweating that result from its administration. Further studies are necessary to explain these findings.

Fig. 1.—Changes in the vital capacity during the precipitation of an asthmatic attack in Subject R. C. with 1.0 mg. of pilocarpine given intravenously. Horizontal line represents time in minutes after the injection. Interrupted vertical line indicates change from one to five minute time intervals.

Intravenous Injection—After the intravenous administration of 1 to 4 mg. of pilocarpine the greatest reduction in vital capacity in most of the patients with asthma occurred in thirty seconds. In a few cases there was a greater reduction three minutes after the administration of the drug. In many cases, after a well established trend in the vital capacity toward the resting levels,

there was an evanescent secondary decrease in vital capacity ten to fifteen minutes after injection. This second reduction, although small, appeared to be a result of the pilocarpine injection since the subjects were well trained and such variations were not ordinarily experienced after histamine and mecholyl. The decrease in vital capacity varied in amount and was never of the same degree as the initial response to the drug. Even in the same subject it varied with successive identical doses of pilocarpine and did not always occur.

In one patient (R C) (Fig 2) a dose of 1 mg of pilocarpine produced a notable reduction in vital capacity, and when a definite trend toward normal, together with subjective improvement, had been established, an asthmatic attack occurred. A marked, further decrease in vital capacity resulted. This attack was readily alleviated by inhalation of aerosolized Isuprel 1-(3', 4' dihydroxyphenyl)-2-isopropylaminoethanol hydrochloride*.

The decrease in vital capacity following the intravenous injection of pilocarpine was greater than that due to intramuscular administration of an equal dose of the drug, but the ratio was variable. In Subject F W, 3 mg of pilocarpine injected intramuscularly produced a reduction in vital capacity of 9 per cent, or 282 ml, whereas an identical dose given intravenously caused a decrease of 18 per cent, or 501 milliliters. On another occasion 4 mg of pilocarpine were given intramuscularly and the vital capacity decreased 8 per cent, or 198 ml, whereas a similar dose by vein caused a reduction of 35 per cent, or 909 milliliters. In another subject (W B) 3 mg of pilocarpine injected intramuscularly reduced the vital capacity 9 per cent, or 292 ml, whereas the same dose given intravenously caused a decrease of 33 per cent, or 1,004 milliliters. In comparison with these studies the reaction of the respiratory tract to Mecholyl chloride given intravenously appeared to be ten to fifty times greater than an identical dose given by the intramuscular route.

In four subjects, 0.5 mg of Prostigmine methylsulfate was administered fifteen to thirty minutes prior to the injection of pilocarpine. In two instances it appeared to augment the action of pilocarpine on the tracheobronchial tree. For example, in Subject J D 2 mg of pilocarpine given intravenously produced a reduction of 291 ml in the vital capacity from the resting level of 2,957 milliliters. When the level had returned toward normal, 0.5 mg Prostigmine was injected by vein and the vital capacity fourteen minutes later measured 2,604 ml, a reduction due to Prostigmine itself of 303 milliliters. A dose of 2 mg of pilocarpine was repeated one minute later and a further reduction of 428 ml was noted. The systemic effects of pilocarpine—namely, flushing, salivation and sweating—also appeared to be augmented by the action of Prostigmine. In two instances Prostigmine did not appear to augment either the tracheobronchial or systemic effects of pilocarpine.

When repeated identical doses of pilocarpine were administered at thirty minute intervals to five subjects, variable results were obtained. In two subjects similar reductions in vital capacity occurred, but in the other three it appeared that with successive doses there was a markedly diminished effect of

*Furnished by Frederick Stearns & Co. Detroit, Mich.

the drug in reducing the vital capacity. For example, in Subject B S (Fig 3) the intravenous injection of 2 mg of pilocarpine caused a reduction of vital capacity to 376 ml from a resting level of 1,996 milliliters. A second injection forty five minutes later produced a reduction to 993 ml and a third dose thirty minutes later reduced the vital capacity only to 1,379 milliliters. The

Fig 3—Comparative effect on the vital capacity of three 0 mg doses of pilocarpine injected intravenously at intervals. Horizontal line represents time in minutes after the injection. Interrupted vertical line indicates change from one to five minute time intervals.

Fig 4—The effectiveness of 0.1 mg. epinephrine given intramuscularly in blocking the reduction in vital capacity caused by the intravenous injection of 4.0 mg of pilocarpine. The horizontal line represents time in minutes after the injection. The interrupted vertical line indicates a change from one to five minute time intervals.

subjective sensation of tightness in the chest also became less with repeated injections. In another subject (F G) a similar trend resulted after four successive injections at thirty-minute intervals, so that the final injection produced no reduction in vital capacity. When the experiment was repeated several weeks later, however, identical doses of pilocarpine produced similar reductions in vital capacity.

Certain antiasthmatic drugs afforded protection in the reactive subjects against the reduction in vital capacity due to pilocarpine. In two cases epinephrine gave pronounced protection against this reduction. Patient F W (Fig 4), for example, had a resting vital capacity of 2,560 ml, and thirty seconds after the intravenous administration of 4 mg pilocarpine it measured 1,651 milliliters. After a gradual return toward normal, 0.3 ml of 1:1,000 epinephrine was injected intramuscularly and five minutes later the vital capacity was 2,686 milliliters. A repeat injection of 4 mg of pilocarpine produced a reduction in vital capacity to only 2,330 ml, and there was a rapid return to the resting level. It was also noted that although epinephrine appeared to prevent the reduction in vital capacity and the subjective and objective changes in the lungs following the administration of pilocarpine, it did not appreciably affect the salivation, flushing, and perspiration resulting from the injection of the drug. In Patient II W epinephrine not only afforded complete protection against the reduction in vital capacity due to pilocarpine but also appeared to reverse the action of the drug. Following the repeat injection of 2 mg of pilocarpine there was an increase of 460 ml in the vital capacity, compared with a decrease of 1,098 ml caused by the same amount of pilocarpine prior to the administration of epinephrine.

Theophylline ethylenediamine likewise prevented the reduction in vital capacity due to pilocarpine. In Subject F G the resting vital capacity measured 3,731 ml, and thirty seconds after the intravenous injection of 3 mg of pilocarpine it measured 2,727 milliliters. When the vital capacity returned to the resting level, 350 mg of theophylline ethylenediamine were given slowly by vein, and ten minutes later the vital capacity was 3,760 milliliters. A second dose of 3 mg of pilocarpine then produced a reduction in vital capacity to only 3,647 milliliters. The systemic reaction to pilocarpine was not altered appreciably.

Bellafoline,* a stable preparation of total levorotatory alkaloids of belladonna leaves, likewise afforded protection against the reduction in vital capacity due to pilocarpine. Patient R C, who had previously suffered an acute asthmatic attack following the injection by vein of 1 mg pilocarpine, was given 0.5 mg of Bellafoline intramuscularly. Ten minutes later an intramuscular dose of 30 mg of pilocarpine produced a decrease in vital capacity of only 53 milliliters. The degree of protection thus afforded the tracheobronchial tree by epinephrine, theophylline ethylenediamine, and Bellafoline was similar to the protection given by the same drugs against Meecholy chloride.¹¹ The other reactions to pilocarpine, such as sweating, flushing and salivation, were only slightly affected by the protecting drugs.

*Furnished by Sandoz Chemical Works Inc New York N Y

It appears that attempts to assay the effectiveness of various anticholinergic drugs by their capacity to prevent the asthma like attacks and the reduction in the vital capacity induced by cholinergic substances would be better carried out with Meecholy chloride than with pilocarpine as the test substance, since the former drug has a more uniform action. Since anticholinergic agents such as atropine and Bellafoline are very effective in preventing this type of induced asthma it would seem worth while to reinvestigate their use in the treatment of spontaneous asthma, especially since other drugs in this group are available which do not have the unfavorable side reactions of atropine. More support for such an investigation is derived from recent data which indicate that in the asthmatic subject the pulmonary reaction to Meecholy chloride may be greater and perhaps more important than the reaction to histamine.³ Confirmation of the pulmonary hyperresponsiveness of asthmatic subjects to cholinergic drugs also suggests that this manner of study should be carried out when surgery on the autonomic nervous supply to the lung is contemplated. It is possible that those subjects who exhibit a more pronounced reactivity to the cholinergic drugs may benefit most by resection of the posterior pulmonary plexus.

SUMMARY

The reaction of the respiratory tract to doses of 1 to 5 mg of pilocarpine in a group of ten normal subjects and seventeen patients with asthma was studied chiefly by measurements of the vital capacity. In two of the normal subjects there was a slight decrease in vital capacity after pilocarpine. In contrast, all the asthmatic patients suffered a reduction in vital capacity after the administration of 1 to 4 mg of pilocarpine intramuscularly or intravenously. After the intramuscular injection of pilocarpine the period of greatest reduction in vital capacity occurred in six to twenty five minutes whereas flushing, salivation, and sweating occurred in a considerably shorter time. The greatest reduction in vital capacity with intravenous pilocarpine usually occurred in thirty seconds, but there was frequently a second reduction ten to fifteen minutes after the injection. Prostigmine appeared to augment the action of pilocarpine in two of four subjects. Epinephrine, theophylline, ethylenediamine and Bellafoline protected the tracheobronchial tree against the reduction in vital capacity due to pilocarpine, but failed to have much effect on the flushing, salivation and sweating due to the drug.

Clinical implications of the study are discussed.

A COMPARISON OF THE TOXIC MANIFESTATIONS PRODUCED BY
BETA DIMETHYLAMINOETHYL BENZHYDRYL ETHER HYDRO
CHLORIDE (BENADRYL) AND TRIPLENNAMINE
(PYRIBENZAMINE)

THOMAS H. MCGAVACK, M.D. F.A.C.P. JONAS WEISSBERG, M.D. AND
LINN J. BOYD, M.D., F.A.C.P.
NEW YORK, N. Y.

THE therapeutic value of antihistaminic compounds in many allergic conditions seems now to be well established. Of these compounds, Benadryl (beta dimethylaminoethyl benzhydryl ether hydrochloride) and Pyribenzamine (N' pyridyl N' benzyl N dimethylethylenediamine) have had by far the most extensive clinical trial. There are a number of other preparations which either in laboratory animals or in man or in both have shown antihistaminic activity equal to or greater than either of these new drugs.^{1,2} Nevertheless until such materials are more thoroughly tested in the human being we must rely mainly upon the two drugs first mentioned whenever an antihistaminic agent is required.

Any comparison of these two substances in human beings is fraught with several difficulties. In the first place the results in animals cannot be transferred quantitatively, and probably not qualitatively to human beings even in regard to the ability of these substances to prevent death from histamine aerosols or anaphylactic shock. Moreover the alkamine ether and tripeleennamine differ in several particulars pharmacologically. The former possesses marked anticholinergic and antibarrum chloride activity; the latter has little or none.^{1,3} Benadryl acts oppositely to tripeleennamine upon the musculature of the duodenum and the uterus. In the human being both exert some hyoscyne like action which is more marked with Benadryl.^{4,5}

Comparisons of the therapeutic efficacy of Benadryl and Pyribenzamine are few in number.^{3,6-11} Claims have been made that dose for dose the drugs are equally effective,^{6,10,11} or that Benadryl⁸ or tripeleennamine^{3,9} is more powerful. One worker who found the latter more active than the former³ has failed to mention the doses used in the comparisons although by inference he has left the impression that that employed for Benadryl was often if not usually, one half to one third that of tripeleennamine. The second investigator, who more consistently observed better effects in some clinical conditions from tripeleennamine, states that the doses of the latter varied from 200 to 400 mg. daily while those for the alkamine ether were usually 200 mg. daily.⁹ Other workers^{6,8} made their comparisons on a weight basis.

There is rather general agreement regarding the nature of the side effects following the use of both Benadryl and tripeleennamine, but there is marked difference of opinion concerning their incidence and severity. To date, all or

Received for publication Nov. 3, 1947.

nearly all of the observations regarding these points have been recorded in the course of treatment of allergic diseases and are therefore subject secondarily to all the influences surrounding the allergic episode. Moreover, there has been no concerted effort to compare the reactions of both drugs in the same subject. Thus the personal equation of the subject has never been eliminated from the final evaluation of the results. In an effort to accomplish these objectives and to afford a sound basis for the comparison of the toxic activity of these antihistaminic compounds over the entire range of therapeutic dosage, the present study was undertaken.

MATERIALS AND METHODS

Ambulatory patients from a general medical clinic of a city hospital were chosen at random except that those with acute illnesses, allergic complaints, or recognizable disturbances of the autonomic nervous system were excluded. The underlying conditions for which these patients sought relief included arthritis, hypertension, arteriosclerosis, and minor upper respiratory, muscular, or digestive complaints. Each subject was further tested for his or her fitness to participate in the investigation by the use of a placebo which resembled the corresponding antihistaminic compound in all its physical characteristics.*

In all, one hundred forty-two subjects, eighty women and sixty-two men ranging in age from 18 to 80 with an average of 41.7 years, completed the test. Of these, fifty-two were studied while taking Benadryl only, fifty-two while receiving tripeleennamine only, and thirty-eight while ingesting successively each of the two antihistaminic compounds. In the last-mentioned subjects a period of fourteen days or more elapsed after one drug had been used before the second was started. Each drug was tried for not less than one week, and any given level of dosage was continued in each subject for not less than one week. A number of subjects were given gradually increasing doses of one or the other drug. The patient continued at each level of dosage for at least one week. Therefore some patients received one or the other of the antihistaminic compounds for periods lasting from four to eight weeks. However, gradually increasing doses of the drug were avoided in the majority of instances, as there was thus produced a tendency to build a tolerance against the unpleasant reactions to the compound.

In order to establish a relatively long-term comparison between the two drugs, each of six subjects was successively followed on gradually increasing doses of first one drug and then the other at daily levels of 150, 300, 450, and 600 mg. respectively. In these subjects each increment in the amount of compound ingested was made after a period of not less than seven days at the immediately preceding level of dosage. Two weeks or more elapsed following the use of one preparation before the other was started.

In Tables I and II the number of patients who developed toxic reactions at each level of dosage and the nature and frequency of various types of reaction

*We wish to express our appreciation to Dr. D. A. Sharp of Puke, Davis & Company, Detroit, Mich., for generous supplies of Benadryl and placebo and to Dr. R. D. Moyer of Ciba Pharmaceutical Products, Inc., Summit, N. J., for a portion of the tripeleennamine.

TABLE I THE NATURE AND INCIDENCE OF TOXIC REACTIONS TO BENADRYL AND PYRIBENZAMINE IN RELATION TO DOSAGE OF COMPOUND USED

DAILY DOSE (MG)	CASES		INCIDENCE AND TYPES OF REACTION

Here are recorded results in 104 patients one half of whom received Benadryl and the other half triptelennamine

are recorded. It will be noted that at the usually employed daily therapeutic dose 150 mg, the incidence of side effects was approximately the same for both drugs. The actual percentages are rather high as contrasted with previously reported results. However since the primary aim was to recognize all unpleasant symptoms rather than to determine therapeutic efficacy a record was made of each manifestation even though present in minor degree.

TABLE II THE INCIDENCE OF UNDESIRABLE EFFECTS IN THIRTY EIGHT SUBJECTS WHO RECEIVED IDENTICAL COURSES OF TREATMENT WITH BENADRYL AND PYRIBENZAMINE, RESPECTIVELY

NATURE OF MANIFESTATION	NUMBER OF PATIENTS SHOWING SYMPTOMS AT THE LEVELS OF DOSAGE INDICATED

* Benadryl.

† Pyribenzamine or triptelennamine.

Of the group of fifty-two subjects who received Benadryl, 77 per cent of the total exhibited some evidence of toxicity, and among the fifty two persons given tripeleennamine only, 67 per cent developed undesirable reactions. An analysis of the results obtained with the thirty-eight individuals who received corresponding doses of both drugs for identical periods of time (Table II, Fig 1) confirmed the findings obtained when entirely different groups of subjects were employed for the testing (Table I). Six subjects, in whom each of the drugs was employed in daily doses of 150, 300, 450, and 600 mg, respectively, for a period of one week or more, did not develop any manifestations of toxicity which persisted or became chronic following the discontinuance of either or both drugs. It was definitely demonstrated that with small doses of each drug, signs

Fig 1—Toxic symptoms produced in a group of thirty eight subjects following the oral ingestion of Benadryl (I) and Pyribenzamine (II) respectively for periods of one week or longer at each of the dosage levels indicated

and symptoms of toxicity were frequent, but mild in degree, both drugs were well tolerated. Drowsiness was more common in connection with the administration of Benadryl, and dryness of the mouth, with tripeleennamine. With Benadryl, a tolerance against drowsiness usually developed in a few days, except with the use of the largest doses when cerebral manifestations became severe. When tripeleennamine was used dryness of the mouth was common and increased in intensity as the daily dose was augmented. Regardless of the amount of drug

employed within the limits noted the majority of the other side reactions to tripeleennamine, such as drowsiness, remained approximately the same. In other words, the tendency to establish tolerance was less than with Benadryl.

DISCUSSION

Both experimentally and clinically tripeleennamine and Benadryl have been demonstrated to possess qualities powerfully antagonistic to histamine. Upon this common feature much of their efficacy in the treatment of allergic disease appears to rest. In addition to this Benadryl shows a minor but still powerful hyoscyne-like action not fully shared by Pyribenzamine. This provides in addition to the antihistaminic effect a mild sedative action which is often desirable in the control of many hypersensitive reactions.

Opportunity has been afforded to utilize human subjects for determining the comparative toxicity of Benadryl and tripeleennamine. The facts that a representative number of these individuals received each of the two drugs at different times and that all observations were checked by the same techniques and personnel lend added emphasis to certain points brought out by an analysis of the data.

1 The high incidence of side effects. All side effects were recorded regardless of their severity. When lower levels of dosage (150 and 300 mg) were used side effects rarely precluded the continued use of the drug. However their frequency prompts a continued search for more nearly ideal agents in the management of the allergic reactions due to histamine.

2 The nature and percentage of side effects produced by each of the two drugs. It is clear from the present study that the intensity and number of cerebral manifestations is greater with Benadryl than with Pyribenzamine. It is equally evident that symptoms referable to the gastrointestinal tract are much more frequent with tripeleennamine than with Benadryl. When the overall incidence of all reactions is assessed there is little difference between the two drugs at lower levels of dosage that is 150 to 300 mg daily. Indeed the greater drowsiness caused by Benadryl is often of therapeutic importance particularly in the itching dermatoses and in asthma. However when higher levels of dosage (450 to 600 mg) are employed Benadryl is decidedly the more toxic of the two drugs (Fig 1) and may cause confusional states not unlike those seen following alcoholic excesses.

From the present studies it seems that far too much emphasis has been placed upon the relatively high incidence of reactions to Benadryl for instance 75 per cent,² as compared with the infrequency of reactions to Pyribenzamine for instance 25 per cent or less.² Indeed in the usual range of therapeutic doses (from 150 to 300 mg daily) a careful study shows that this wide difference does not exist. Moreover, many of the unpleasant symptoms produced by Benadryl in such amounts are actually accounted for by its sedative action, which may sometimes be profitably employed in therapy. At higher levels of dosage Benadryl becomes definitely the more toxic of the two antihistaminic substances under

discussion (Fig. 1) and should be used at such levels only when the patient can be under more or less constant surveillance. The gastrointestinal irritation of tripeleminamine at similarly high levels of dosage usually precludes its use in the majority of patients.

3. Is there a direct relationship between toxic reactions and the antihistaminic effect? If this question is answered in the affirmative, one would expect that therapeutic effectiveness and toxicity would vary directly. However this is not the case. It seems likely, therefore, that the antihistaminic factor is not responsible for the untoward symptoms, but that some other property of each of these drugs plays a dominant role in producing side effects. This apparent dissociation between antihistaminic and toxic properties of these drugs furnishes a real incentive to continue the search for agents which will possess the antihistaminic factor to the complete or nearly complete exclusion of the toxic factor.

SUMMARY AND CONCLUSIONS

One hundred forty-two subjects without allergic disease or known disturbances of the autonomic nervous system were given Benadryl and tripeleminamine (Pyribenzamine), respectively, in doses ranging from 150 to 600 mg daily.

Of 52 subjects to whom tripeleminamine alone was given, thirty-five, or 67 per cent, developed one or more toxic symptoms. Of an equal number of subjects to whom Benadryl alone was administered, forty, or 77 per cent, showed some type of untoward reaction.

In thirty-eight patients the effects of both Benadryl and tripeleminamine were determined and comparisons of the effects of the two drugs were made on a weight for weight basis. The total number of reactions to Benadryl was sixty, and to tripeleminamine, sixty-three. When 450 mg or less of the drug were given, Benadryl showed definitely fewer reactions than did Pyribenzamine, but above that figure Benadryl produced a decidedly higher incidence of reactions.

Benadryl produced a preponderance of its disturbances in the sensorium, tripeleminamine showed a predominance of gastrointestinal manifestations.

Usually the side effects did not preclude the therapeutic application of either drug in daily doses of 300 mg or less. With Benadryl, initially unpleasant responses may disappear after the drug is continued for several days.

Both drugs are highly useful antihistaminic substances in the control—of a number of allergic diseases. In the usual range of dosage the incidence of side reactions is approximately equal and their intensity so mild as rarely to preclude their continued use. Indeed, the cerebral depression caused by both drugs, but more especially by Benadryl, may frequently add to the range of therapeutic applicability.

EVALUATION OF A NEW SEDATIVE DRUG (3,3-DIETHYL-2,4-DIOXOPIPERIDINE)

AARON E. PARSONNET, M.D., ARTHUR BERNSTEIN, M.D., AND
EMANUEL KLOSK, M.D., NEWARK, N. J., AND ERICH HIRSCHBERG, M.S.,
SAUL H. RUBIN, PH.D., AND LEO A. PIRK, PH.D., NUTLEY, N. J.

WITH THE TECHNICAL ASSISTANCE OF MARTHA FINE GREENBERG, B.A.

MOST physicians are confronted daily with the need of sedative medication for many of their patients. The value of the bromides and barbiturates is firmly established. However, these drugs occasionally produce side reactions such as rashes, headache, and lassitude. Moreover, continued use of the barbiturates may lead to tolerance or addiction. In the light of the foregoing, a new sedative which is distinguished by clinical effectiveness and good tolerability deserves consideration. Consequently, we set out to evaluate such a compound (3,3-diethyl-2,4-dioxopiperidine) submitted to us under the designation of NU-1510 and later under the name of Sedulon.*

The pharmacology of this substance and its oxidation product, 3,3-diethyl-2,4-dioxotetrahydropyridine, was thoroughly explored by Koppanyi, Herwick, Linegar, and Foster.³ According to these investigators both compounds, in appropriate doses, produce motor paralysis, muscular relaxation, loss of righting reflexes, and deep sleep in experimental animals. The onset of action with the piperidine derivative is somewhat slower and its effect weaker and longer lasting than with the pyridine compound. From the figures presented by these workers it appears that, administered intravenously to rabbits, the narcotic index (LD_{50}/ND_{50})† of the piperidine derivative is 3.42, that of the pyridine compound, 4.07, and that of barbital, 2.96. Thus, the relative order of safety was found to be pyridine derivative > piperidine compound > barbital. There were no significant changes in hemoglobin, erythrocyte count, leucocyte count, or differential count when daily doses of the pyridine derivative and the piperidine compound, respectively, were fed to rabbits for several weeks.

3,3-Diethyl-2,4-dioxotetrahydropyridine was evaluated clinically by Polatin and Horwitz² in psychiatric cases and by Friedl¹ in mentally normal patients requiring sedative-hypnotic medication. These workers found the pyridine derivative to be a mild but very effective somnifacient. As a daytime sedative it generally proved adequate in patients with nervous tension.

From the Newark Clinical Group, the Medical Service of Dr. A. E. Parsonnet, Newark Beth Israel Hospital, Newark, N. J., and The Nutrition Laboratories and The Medical Department, Hoffmann-La Roche Inc., Nutley, N. J.

Received for publication Oct. 30, 1947.

*We are indebted to Hoffmann-La Roche Inc., Nutley, N. J., for supplies of NU 1510 (Sedulon) in the form of scored tablets of 0.25 gram.

† LD_{50} is defined as the lethal dose for 50 per cent of the animals and ND_{50} as the narcotic dose which prevents a righting response in 50 per cent of the animals after the tail is pinched.

Because of its weaker and more prolonged action as evidenced in animal experiments, 3,3 diethyl 2,4-dioxopiperidine held promise of being at least as satisfactory as its oxidation product for daytime sedation and it was in this direction that a study was instituted.

The clinical work is presented in Part I which gives results in patients requiring sedative medication. Part II gives the work done in man on urinary excretion following the administration of 3,3 diethyl 2,4 dioxotetrahydropyridine and of 3,3 diethyl 2,4 dioxopiperidine.

PART I

BY AARON E. PARSONNET, ARTHUR BERNSTEIN AND EMANUEL KLOSK

The initial program called for an intensive study of a small group of subjects. Twelve patients with a diagnosis of essential hypertension were chosen. There were five men, ranging in age from 49 to 64 years, and seven women whose ages ranged from 27 to 56 years. Some of these patients had cardiac symptoms such as angina of effort, dyspnea and palpitation; others complained merely of the frequent headaches and nervous manifestations so often endured by the hypertensive patient. All of them had been taking $\frac{1}{4}$ to $\frac{1}{2}$ gram of phenobarbital three or four times a day for periods ranging from several months to a number of years and were thus suited for a comparative study.

Phenobarbital and all other medication were discontinued. Sedulon was substituted and the original plan of studying these subjects over a period of approximately two months was followed with but minor deviations. It was explained to each patient that he was going to receive a drug which might have an effect on the blood pressure but no mention was made of sedative action. Deliberately their attention was diverted and all questions related to the sedation attained were injected casually in the course of subsequent interviews. It was thought that there was no need for alternating Sedulon and placebo medication since phenobarbital known to the patients as exerting a sedative effect was replaced by a drug which they expected to have a hypotensive but not a sedative action. Consequently any results in the latter direction were probably not conditioned by a psychological influence.

Treatment of eleven subjects was instituted with doses of 0.125 Gm. but only in one did this amount suffice to induce good sedation. The other ten subjects complained of nervous tension on a total daily dose of 0.375 Gm. and this was therefore doubled. However the increase was not ordered before these patients had been on the lower dose for from three to four weeks and the change was effected always at an interview when there was no complaint about inadequate sedation.

One patient did not return for re-examination after she was placed on 0.25 Gm. three times daily. Of the nine subjects who were followed further seven derived good sedation from a total daily dose of 0.75 Gm. and in two only fair sedation was induced. A twelfth patient received initially 0.25 Gm. three times a day and this was attended by satisfactory sedation.

The action of Sedulon commenced thirty to sixty minutes after its intake and lasted from three to four hours following each dose. The effect was found

to be of a selective sedative nature without marked soporific action. This quality is an advantage since doses of phenobarbital which were productive of a similar degree of sedation commonly rendered the patients sleepy at the same time.

The patient deriving good sedation from only 0.375 Gm. per day complained of pruritus, which was first thought to be due to the medication. With diavial of the drug, however, failed to result in subsidence of the pruritus which was finally relieved by psychotherapeutic measures. Reinstitution of Sedulon was not attended by recurrence of the pruritus. Similarly, there were no ill effects in any of the other patients.

Blood pressure readings for all subjects were done at frequent intervals. As can be seen from the average values in Table I, there was no significant reduction in either the systolic or the diastolic blood pressure.

TABLE I
AVERAGE BLOOD PRESSURE READINGS AND HEMATOLOGIC FINDINGS IN TWELVE
HYPERTENSIVE PATIENTS TREATED FOR FROM FOUR TO EIGHT WEEKS WITH
3,3 DIETHYL 2,4 DIOXOPIPIDINE (SEDULON)

	BEFORE TREATMENT	AFTER TREATMENT	RANGE OF WEEKLY AVERAGES	
			MINIMUM	MAXIMUM
Blood pressure	192/108	184/107	91	98
Hemoglobin (per cent) (Suhl)	91	96	91	98
Blood cell counts				
Erythrocytes (millions/c. mm.)	4.16	4.46	4.37	4.18
Leucocytes (millions/c. mm.)	7.64	8.13	7.04	9.13
Polymorphs (per cent)	59.4	61.8	54.0	66.7
Lymphocytes (per cent)	30.1	28.6	22.7	37.3
Monocytes (per cent)	7.4	7.4	6.5	9.0
Eosinophils (per cent)	2.7	2.6	2.6	3.0

Urinályses carried out every week did not reveal any changes as compared with the premedication findings.

A special effort was made to determine the effect, if any, of the prolonged treatment with Sedulon on the blood picture. Hemoglobin determinations and red, white, and differential counts were done for all patients initially and at weekly intervals. As can be seen from Table I, which lists the average findings before and after treatment as well as the range of weekly averages, there were no significant changes in the hemograms during this period of close observation which included eight blood counts for most of the patients.

These gratifying results prompted us to extend the initial program.

Sedulon was thus continued in eight of the original group of twelve patients (Table II). Including the initial trial period, these eight subjects remained on the experimental drug for from six months to almost one year. In Patient 4 a total daily dose of 0.375 Gm. continued to induce good sedation for nearly eleven months, that is, up to the time the patient last reported for reexamination. The other seven subjects, each of whom received 0.25 Gm. three times a day, continued to derive the same degree of sedation during this period or extended trial as they did initially, that is to say, in Patients 1, 7, 9, 10, 11, and 12, good sedation was induced, and fair sedation resulted in Patient 8. Ill effects were absent and none of the subjects developed signs of tolerance or addiction.

TABLE II BLOOD STUDIES IN EIGHT HYPERTENSIVE PATIENTS RECEIVING SEDULON FOR FROM SIX MONTHS TO ALMOST ONE YEAR

PATIENT	MEDICATION (MO.)	HEMOGLOBIN (PER CENT) (SAHL)	ERYTHROCYTE COUNT (MILLIONS/C MM.)	LEUCOCYTE COUNT (THOUSANDS/C MM.)

	6	81	4.30	6.20

0 The figures listed are premedication findings

During the period of extended trial hemograms were done for all eight patients at irregular intervals. Table II correlates some of the premedication blood findings and the findings after several months of medication. There occurred a decrease in the hemoglobin values and the erythrocyte counts in two patients (Patients 4 and 9) and a drop in hemoglobin values as well as in the red and white cell counts in one patient (Patient 7). However Patient 4 was on a rice diet at the time of the shift in the red blood picture and Patient 7 underwent a cholecystectomy in May 1947. In the former reinstitution of a normal diet was followed by an increase in both the hemoglobin value and the red cell count, and all the values of the last count recorded for Patient 7 at a time when she had completely recovered from the operation approximated the original findings. As for Patient 9 the erythrocyte count had dropped from 5,230,000 to 4,300,000 and the hemoglobin value had decreased from 104 to 86 per cent after more than six months of Sedulon intake. However there was no further reduction in the number of red blood cells during the ensuing four months in spite of continued Sedulon medication and the hemoglobin value increased appreciably during this time. It is concluded that none of these changes is attributable to the administration of the drug.

In further extension of the original program the preparation was given to fifty patients complaining of nervousness, irritability or emotional instability. In this group no blood studies were performed but each patient was seen daily regularly. The dosage was 0.25 Gm. three times daily and most of these fifty

patients have been taking the drug for from three to five months. While good or fair sedation resulted from this regimen, generally the patients were not over-sedated. However, in one patient it became necessary to reduce the dosage to 0.125 Gm. three times a day, and this dose was attended by satisfactory sedation. One patient developed some dizziness and nausea after taking the drug for about one month. Twenty-four hours after discontinuation of the medication, these symptoms subsided and did not reappear when Sedulon was reinstituted forty-eight hours later. However, since this patient was apprehensive about continuing the drug, it was stopped several days thereafter. Among the fifty subjects of this group there was one patient who had previously developed dermatitis from the use of phenobarbital. In contrast, Sedulon, which she has been taking for three months, is tolerated without untoward effects.

PART II

By ERICH HIRSCHBERG, SAUL H. RUBIN, AND LEO A. PIRK

As was shown by Klautwald and co-workers,⁵ there are no indications that 3,3-diethyl-2,4-dioxopiperidine is excreted unchanged in the urine when this compound is fed to dogs at a dosage level of 200 mg. per kilogram. However, these workers did recover between 7 and 8 per cent of the amounts of the administered piperidine derivative in the form of its oxidation product—3,3-diethyl-2,4-dioxotetrahydropyridine. The following structural formulas illustrate this transformation of the piperidine into the pyridine compound.

With a new fluorimetric method² (a modification of that described by Kubli and Schmidt⁴) for the determination of this pyridine derivative in urine at our command, it was decided to study its renal elimination in man following the administration of 3,3-diethyl-2,4-dioxopiperidine. It seemed of particular interest to compare the amounts of the pyridine derivative excreted after the intake of the piperidine compound on the one hand, with those following the administration of similar doses of the pyridine compound on the other.*

*For the sake of simplicity, 3,3-diethyl-2,4-dioxopiperidine is referred to as Sedulon, and 3,3-diethyl-2,4-dioxotetrahydropyridine as NU-903, the designation under which the latter compound was supplied by Hoffmann-La Roche Inc., Nutley, N. J.

Four normal, male volunteers (physicians) ranging in age from 24 to 32 years were chosen. Collection of twenty-four hour urine specimens was instituted seven days prior to the initiation of the excretion experiment proper and continued daily for five weeks. On the eighth evening each subject received 0.6 Gm of NU 903 and after one week without further medication this dose was repeated. Again following a medication-free interval of seven days 0.75 Gm of Sedulon was given to each of the volunteers and a second identical dose was given at the end of the fourth week with subsequent collection of urine specimens for another week.

Amber bottles containing approximately 5 cc of toluene were used for pooling the daily voidings of each subject. In carrying out the estimations of the urinary excretion of NU 903 in all the specimens thus obtained the method described by Hirschberg and co-workers² was used. This technique is based on the measurement of the comparative fluorescence of urines at suitable dilutions in the absence and presence of hydroxylamine. The difference in intensity between total fluorescence (without hydroxylamine treatment) and residual fluorescence (with hydroxylamine treatment) yields a measure of the concentration of NU 903 in urine. Sedulon is nonfluorescent under these conditions.

Fig. 1—Urinary excretion of 3,3-diethyl-4-dioxotetrahydropyridine (NU 903) for Subject L. K. receiving at weekly intervals two single doses of 0.6 Gm of 3,3-diethyl-4-dioxotetrahydropyridine (indicated by arrows) and two single doses of 0.75 Gm of 3,3-diethyl-4-dioxopiperidine (Sedulon) (indicated by arrows with dots). The initial estimation was carried out seven days prior to the administration of the first dose of NU 903 and subsequent assays were performed daily for five weeks.

Urine specimens of persons who had not received either the pyridine or the piperidine compound were found to show some difference in intensity of total fluorescence and residual fluorescence after hydroxylamine treatment. This observation was the reason for testing seven premedication voidings of each of the four subjects. Thus, average correction factors for hydroxylamine reactive

substances exhibiting irrelevant fluorescence were obtained. Calculated in milligrams of NU-903 per day, these correction factors were

SUBJECT	
E K	$3.9 \pm S.D. 4.3$
M L	$6.8 \pm S.D. 3.3$
D S	$-0.6 \pm S.D. 6.0$
E S	$7.7 \pm S.D. 3.9$

It can be seen that the amounts of hydroxylamine-reactive substances excreted differed from subject to subject, in one subject (D S) the fluorescence of the hydroxylamine-treated specimens was even slightly greater than that of the untreated urine specimens. However, in the individual subjects the quantities of irrelevant interfering substances were sufficiently constant from day to day to permit the use of the correction factors. Consequently all findings were corrected accordingly.

Fig. 2—Urinary excretion of 3,3-diethyl-2,4-dioxotetrahydropyridine (NU 903) for subject D S receiving at weekly intervals two single doses of 0.6 Gm of 3,3-diethyl-2,4-dioxotetrahydropyridine (indicated by arrows) and two single doses of 0.75 Gm of 3,3-diethyl-2,4-dioxopiperidine (Sedulon) (indicated by dots). The initial estimation was carried out seven days prior to the administration of the first dose of NU 903 and subsequent assays were performed daily for five weeks with the exception of two days (indicated by broken lines) when the specimens were lost.

Figures 1 and 2 illustrate the procedure and the daily excretion values of NU-903 during the five weeks of experimentation for two subjects. The first two periods shown demonstrate the excretion of the pyridine compound following its administration, the last two periods show the elimination of the pyridine derivative following the administration of the piperidine compound. As can be seen, significant quantities of NU-903 were also eliminated following the ingestion of Sedulon.

The total amounts of NU 903 excreted in seven day observation periods by four subjects following each of two doses of NU 903 and two doses of Sedulon are recorded in Table III.

It can be seen from Figs 1 and 2 that both drugs are excreted rapidly with the main portions of the eliminated amounts of NU 903 appearing in the first and second twenty four hour urine specimens collected after the intake of both compounds. Three to four days following the individual doses only negligible quantities of NU 903, if any, were detectable in the urine. Rapid elimination was observed also in the two other subjects.

TABLE III. URINARY EXCRETION OF NU 903 FOR FOUR NORMAL SUBJECTS AFTER SINGLE DOSES OF 0.6 GM. OF NU 903 AND AFTER SINGLE DOSES OF 0.75 GM. OF 3:3 DIETHYL 2:4 DIOXYPYPERIDINYL (SEDULON)

SUBJECT	E	E ₂	AVERAGE	E ₂	E	AVERAGE
E. K.	77	65	71	90	41	66
M. L.	66	41	54	84	15	50
D. S.	33	43	38	75	11	43
E. S.	60	51	56	43	40	42
Average			55			50

D. The total excretion of NU 903 in milligrams following the first dose of NU 903

L. The total excretion of NU 903 in milligram following the second dose of NU 903

S. The total excretion of NU 903 in milligrams following the first dose of Sedulon

1. The total excretion of NU 903 in milligrams following the second dose of Sedulon

As appears from Table III the total excretion values after each of the eight individual doses of NU 903 varied considerably ranging from 33 to 77 milligrams. However in a given subject the total excretion values recorded following the two individual doses of the pyridine compound were in fair agreement. For instance for Subject D. S. these values were 33 and 43 mg. respectively. The greatest difference was observed in subject M. L. who following the second dose of NU 903 excreted 38 per cent less than after the first dose.

It can be seen likewise from Table III that the total excretion values of NU 903 following each of the eight individual doses of Sedulon ranged from 11 to 90 milligrams. Thus these total excretion values varied even more than those recorded after the intake of NU 903. Moreover the total amounts of the pyridine compound eliminated by a given subject following the two individual doses of Sedulon differed appreciably. For example Subject D. S. whose excretion values after the two doses of NU 903 were in fair agreement excreted 11 mg. of NU 903 following the second dose of Sedulon as compared with 75 mg. after the first dose a reduction of 85 per cent.

In general the average of the two excretion values recorded for a given person following the administration of NU 903 was somewhat higher than the average of the two excretion values for that subject after the intake of Sedulon. The mean value of the average amounts of NU 903 excreted following 0.6 Gm. of NU 903 was 55 mg. or 9.2 per cent of the injected dose and the mean value of the average amounts of NU 903 eliminated after 0.75 Gm. of Sedulon was 50 mg. or 6.7 per cent. It seems that the elimination of NU 903 following the intake of this drug is slightly greater than after the ingestion of the piperidine compound.

The urinary excretion of NU-903 following administration of this compound was studied in man by Polatin and co-workers⁶. These investigators, too, reported that following a single dose of 0.6 Gm the excretion level dropped promptly. For the six psychiatric patients whom they studied, the mean value of the total amounts eliminated over four days was 61 mg or 10.1 per cent of the ingested amount. This is in good agreement with the present findings.

Similarly, the extent of elimination of the pyridine compound reported by Kiautwald and associates⁵ in dogs after the administration of 3,3-diethyl-2,4-dioxopiperidine approximates closely that determined for the four subjects in the present investigation, the excretion was 7 to 8 per cent of the amount fed to the animals as compared with a mean value of 6.7 per cent of the dose given to the human subjects.

Since the average excretion of NU-903 following the intake of this drug on the one hand and after the ingestion of Sedulon on the other appears to be of the same order of magnitude, it may be tentatively concluded that most or all of the piperidine compound administered is converted into the pyridine derivative.

The oxidation of the piperidine compound in the organism is suggestive of its mode of action. The belief that transformation of 3,3-diethyl-2,4-dioxopiperidine to the corresponding pyridine compound precedes its action is supported by both the somewhat slower onset and the longer duration of the effects of the former.³

SUMMARY OF PARTS I AND II

A new sedative drug, 3,3-diethyl-2,4-dioxopiperidine (Sedulon), was evaluated clinically in a total of sixty-two patients requiring sedation, twelve of whom had hypertension. Eleven of these subjects received 0.125 Gm three times a day as the initial dose, but only one derived good sedation at this dosage level. With a dosage of 0.25 Gm three times daily, good sedation was obtained in nearly all of the sixty-two cases. The effect of prolonged medication on the blood picture was studied in the twelve hypertensive patients receiving total daily doses of 0.375 and/or 0.75 Gm for two months. Hemograms at weekly intervals showed no significant changes in either the red or the white blood picture. In eight of these patients, Sedulon was continued so that they received the drug for from six months to almost one year with no untoward effect on the blood picture. In none of the sixty-two cases was the administration of Sedulon attended by untoward effects. The drug failed to reduce the blood pressure in the twelve patients with hypertension.

Both Sedulon and its dehydrogenation product, 3,3-diethyl-2,4-dioxotetrahydropyridine (NU-903), are rapidly excreted in the urine as NU-903. Four human subjects excreted an average of 9.2 per cent of each of two doses of 0.6 Gm of NU-903 taken seven days apart. Subsequently, they excreted average amounts of NU-903 equivalent to 6.7 per cent of each of two doses of 0.75 Gm of Sedulon taken at weekly intervals.

VARIATIONS IN DERMAL ABSORPTION WITH AGE

J STRAUSS, JR, AND H NECHELES
CHICAGO, ILL

THE activity of various bodily processes differs with age. It should be anticipated, therefore, that the rate or pattern of absorption of fluids from the skin will reflect these variations.

It is the purpose of this report to describe definite variations in the absorption of a dye from an intradermal site of injection, the variation apparently being related chiefly to the age of the subject rather than to specific disease entities.

A review of the literature reveals that various aspects of this problem have received considerable attention. McClure and Aldrich^{1,2} utilized the disappearance time of intradermally injected normal saline solution as a test of edema in nephritic children. They observed a more rapid disappearance (to palpation) of the wheal than in normal controls. This test was extended to a variety of pathologic conditions. A shorter disappearance time was observed in scarlet fever and diphtheria,^{3,4} lobar pneumonia,⁵ jaundice,⁶ tuberculosis,⁷ serum sickness,⁸ toxemia of pregnancy,⁹ and peripheral circulatory deficiency.^{10,13} The disappearance time was found to be shorter in thyrotoxicosis¹⁴ and prolonged in myxedema.¹⁵ The work of Aldrich and McClure on children was confirmed by Feldman and Reitsneider¹⁶ in adult nephritic patients. Beig¹ noted faster rate of disappearance in diabetic subjects, paralleling the severity of the diabetes, but this could not be confirmed by Levy and Rynes.¹⁸ Olmstead¹⁹ in a study of children with heart disease, found the test of prognostic value in severely ill or toxic patients.

Thompson¹⁰ stated that the circulation had little to do with dermal absorption of saline solution and concluded that the actual mechanism was unknown. Olmstead¹⁹ also advanced this view, noting that disappearance time post mortem was not increased. White and Irvine-Jones²⁰ likewise concluded that circulation played no part, on the basis of their observations of the effect of altered blood flow, temperature changes, and adrenalin. They did not agree with Olmstead, however, in regard to an unaltered disappearance time post mortem.

White and Irvine-Jones²⁰ and Taylor²¹ found intradermally injected fluid in the corium. McMaster and Hudack^{2,24} who studied intradermally injected vital dyes in animals and humans, stated that intradermal injections are largely intralymphatic, the dyes entering lymphatics injured by the injecting needle. They observed that the dyes gradually spread through the superficial lymphatics.

From the Department of Gastro-Intestinal Research, Medical Research Institute of Michael Reese Hospital and the Department of Medicine of Michael Reese Hospital.
The Department is in part supported by the Michael Reese Research Foundation.

Aided by a grant from the A. B. Kuppenheimer Fund.

Received for publication Jan. 14, 1948.

*Our attention was drawn to this problem by observations of Dr. H. Sorter from this hospital that blood penicillin levels (following intramuscular administration) frequently were lower initially and higher late in old patients than in young patients.

and stated that differences in the spread were due to differences in skin texture in different subjects which caused the needle either to fail to reach a lymphatic plexus or to penetrate beyond it. In either case however the dyes reach large deeper lymphatics draining the injected area. Factors increasing lymph flow increased the rate of dye diffusion. Hudack and McMaster²⁴ pointed out that any local injection soon becomes a general one since the injected material enters the blood stream rapidly. This is borne out by the appearance of phenol red in the urine within fifteen minutes after intradermal injection.² White and Irvine Jones⁹ were able to dismiss certain factors such as hydrogen ion concentration, potassium/calcium balance and osmotic pressure as being of significance in the absorption of normal saline solution from the skin. They felt that the disappearance of the intradermal wheal was due simply to diffusion and although they observed that artificially produced edema differed from nephritic or cardiac edema in that it did not produce an increased disappearance rate they were unable to find the effective absorptive factor. In this connection it is interesting that McMaster² found lymph stasis in cardiac edema and increased lymph flow in nephritic edema although in both instances the lymphatics are widened. In a recent article Kurziok and co-workers²⁵ referred to the work of Hoffman and Duran Reivals on a factor which increased intradermal spread of various substances. Originally found in testicular extract it was also found in certain bacteria, snake venom and malignant tissue. This spreading factor acting on connective tissue by hydrolysis of hyaluronic acid salts is an enzyme hyaluronidase. These authors concluded that the factor (enzyme or enzymes) causing diffusion in the dermis is identical with that exhibiting hyaluronidase activity.

SUBJECTS AND METHODS

The subjects were not selected except that due to the nature of the test most were of the white race. Sex distribution was approximately equal. No severely ill patient was used and most were well enough to be either ambulatory or semiambulatory. One hundred and one of the subjects could be considered normal in regard to cardiovascular system and skin. This group included a number of subjects who were either in normal health (hospital staff) or could be assumed to be healthy such as surgical patients hospitalized for elective operative procedures. The conditions of the rest of the subjects (26 per cent) were such as would be encountered in the medical and surgical wards of any large general hospital. The experimental data obtained on these patients fell within the range of the normal controls in each group and it was apparent upon analysis of all data that age rather than a particular disease was the chief determining factor in dermal absorption. On the basis of the accumulated data it was seen that the entire series could be divided into groups each covering a period of fifteen years. The data on each age group were compared for statistically significant differences by the chi square test (Fisher) using a 5 per cent level of significance. Under Results we refer to this analysis when differences are called statistically significant.

One tenth cubic centimeter of a sterile solution of Evans blue in normal saline (0.05 mg. per cubic centimeter) was injected intracutaneously on the middle third of the volar surface of the forearm using a short No. 25 hypodermic needle and a tuberculin syringe. One of us (J. V.) made all injections and readings. Four periodic measurements were made on each subject. This was done by placing a strip of clear celluloid film over the wheal or lye stain and marking out the pattern. It was usually necessary to emphasize the dye outlines with

We are obliged to Dr. H. Silverstein for help in the statistical work.

TABLE II INITIAL WHEAL AREA

AGE GROUP (YR.)	PER CENT OF CASES WITH WHEAL AREA GREATER THAN 0.5 SQ. CM.
0-15	8
16-30	30
31-45	50
46-60	56
61-75	58
76-90	67

It is seen in Tables III and IV that the same general pattern continues at the end of four hours except in the 16 to 30 year age group where there is a trend toward a decrease in the wheal size which however, was found to have borderline statistical significance only.

TABLE III DISTRIBUTION OF WHEAL AREAS FOUR HOURS AFTER INJECTION

AGE GROUP (YE)	AREA OF WHEAL IN SQUARE CENTIMETERS																	NUMBER OF CASES IN EACH AGE GROUP															
	0	3	4	0	5	0	6	0	7	0	8	0	9	1	0	1	1		2	1	3	1	4	1	5	1	6	1	7	1	8	1	9

0-15	39
16-30	20
31-45	44
46-60	50
61-75	63
76-90	67

It is further apparent, as shown in Table V, that visible dye remains in the injected area of a significantly larger number of persons in the younger age groups. The two groups from 10 to 14 and from 15 to 29 years of age had visible dye left in 90 to 97 per cent of the cases while the two older groups had visible dye in 57 to 79 per cent.

DISCUSSION

In young persons the initial wheal was smaller than in older persons (Tables I to IV). On the other hand, the dye remained longer in the skin of the younger subjects (Table V). Usually the size of the initial wheal increased in younger persons before it disappeared, while in older subjects it usually decreased steadily. These results are not readily explained. Lymphatic absorption may play a larger role than absorption into the venous blood.²⁴ It has been stated that the number of skin capillaries diminishes with age,² and one might assume that the number of lymphatic vessels diminishes likewise. Thus, in younger subjects lymphatic absorption may be greater in the initial phase of skin absorption than in older subjects.

Differences in texture of the skin between old and young persons are so distinct that they may well explain some of the phenomena observed. In the young, skin turgor is high and there are more elastic fibers present. In the old, turgor is low, elastic tissue is reduced, the epidermis and the deeper layers of the skin atrophy, and the skin has folds and consequently a greater surface area. In our tests it was easy to inject 0.1 cc. of dye solution into the skin of older persons, but in the youngest group it was hard to push the needle through the skin and much more pressure had to be exerted to push the fluid into the skin. On a physical basis these differences may explain the larger initial wheals in the older subjects and the smaller ones in the younger subjects. Also, a possibly more rapid initial absorption in the younger group may be explained by the higher initial pressure in the wheal. On the other hand, the longer secondary persistence of dye in the skin of the younger group (Table V) may be explained by the relatively smaller area of the wheal and a consequently smaller absorbing area in which the dye is contained. In the older subjects the ready spread of the dye opens a larger absorbing area, initial absorption may be poor due to fewer lymphatic vessels, lesser pressure, possibly less tissue damage, less motility of the skin, and consequently less lymphatic suction, but the secondary stage of absorption (twenty-four and forty-eight hours) may be faster, due to the greater area occupied by the dye.

We have discussed mechanical factors mainly. Chemical factors, such as differences in hyaluronic acid salts and hyaluronidase, in histamine liberation, in water and salt content of the skin, in proteins that bind the dye, in macrophages, and so on, of old as compared with younger people are even more unknown than physical factors.

SUMMARY

Differences in the absorption pattern of intradermally injected Evans blue in different age groups were demonstrated.

FURTHER STUDIES ON THE WELTMANN SERUM COAGULATION REACTION

LEO H. SIEGEL, M.D., AND MANFRED KRAEMER, M.D.
NEWARK, N. J.

IN 1942 one of us (M. K.)¹ presented a study on the clinical significance of the Weltmann serum coagulation reaction, using as subject material the results of the reaction as tested in over 1,100 patients. Baker² shortly thereafter reported further results from Kraemer's laboratory. The present report is a continuation of those studies, covering the Weltmann reaction in over 3,000 cases.

Weltmann,^{3, 4} in 1930, described a serum coagulation reaction which has shown itself to be of considerable clinical significance. He found that when normal human blood serum was diluted with distilled water 1:50 and boiled, the proteins failed to coagulate. However, when a small amount of electrolyte such as calcium chloride, magnesium chloride, or barium chloride was added, coagulation occurred. In certain pathologic conditions Weltmann noted that the serum required greater than normal concentrations of electrolyte in order for protein coagulation to occur, while in other conditions less than the normal concentration of electrolyte was required for coagulation. If 0.1 ml. of normal serum was added to 5 ml. of 0.4 per cent calcium chloride solution and boiled, the protein coagulated. However, if the serum was added to 0.2 per cent calcium chloride, coagulation did not take place.

Exudative and inflammatory processes so altered the blood serum that coagulation of the protein occurred only in concentrations of calcium chloride higher than 0.4 per cent. Conversely, fibrosing processes so altered the serum that coagulation occurred in concentrations of calcium chloride lower than 0.4 per cent. From these findings Weltmann devised the relatively simple test described below.

Various theories were propounded to explain the mechanism of the Weltmann reaction. Alterations in the following factors, either singly or in combination, were suggested as the basis of the reaction: the pH of the calcium chloride solutions employed, the pH of the serum, the serum calcium concentration, the total blood globulin, the albumin-globulin ratio, and the blood fibrinogen.⁵ Dees studied the reaction extensively^{6, 8} and suggested that the serum lipids are an important factor in the coagulation reaction. However, Scheelis and Levy⁵ showed that the coagulation reaction is closely related to changes in the percentage of alpha globulin in the blood.

From the Presbyterian Hospital.

Read at the Meeting of the Eastern Section of the American Federation for Clinical Research, Cornell University, New York, Dec. 12, 1947.

All technical procedures were performed by Miss Margaret Palmer.

Received for publication Dec. 20, 1947.

TECHNIQUE

Ten test tubes are set up in a rack and are numbered 1 to 10 from left to right. From a stock solution of 1 per cent calcium chloride ($\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$) measured amounts are pipetted into each tube starting with 5 ml in the first tube and decreasing by 0.5 ml in each tube so that tube 10 contains 5 milliliters. Sufficient distilled water is added so that each tube will contain a total of 5 ml of solution, that is 4.5 ml of water are added to tube 10, 4 ml to tube 9 and so on in decreasing amounts to 5 ml in tube 2. This procedure results in ten dilutions of calcium chloride ranging from 1 per cent in tube 1 down to 0.1 per cent in tube 10.

To each tube is then added 0.1 ml of the blood serum to be tested. The serum must be unhemolyzed. After shaking the tubes in their rack are placed in a boiling water bath for exactly fifteen minutes. The rack of tubes is then removed from the bath and the number of tubes in which coagulation has occurred is recorded. The coagulum appears as a flocculation. Coagulation normally appears in the tubes of higher concentration (Tubes 1 to 6) and not in the tubes of lower concentration (Tubes 7 to 10). The number of the tube containing the most dilute solution of calcium chloride in which coagulation has occurred gives the reading for the test. Thus if coagulation occurs in tubes 1 through 6 the coagulation band is 6 (C B 6 or Weltmann 6). Care must be taken to determine the last tube in which *actual* coagulation has occurred since clouding or turbidity may occur in two or three tubes more dilute than the significant tube. With normal human serum coagulation usually occurs in the first 5 to 7 tubes (C B 5 or 6 or 7). When the coagulation band is less than 5 it is said to shift to the left and when it is more than 7 it is said to shift to the right.

In actual practice we have simplified this technique to ease the burden on the technician without sacrificing accuracy. If coagulation occurs in any tube by definition it will also occur in every tube to the left of it (that is in all higher concentrations). Therefore tubes 1, 2, 9 and 10 are not routinely set up since coagulation usually occurs in at least three tubes and rarely occurs in more than eight tubes. If, after the initial test is performed, no coagulation has occurred in tube 3, tubes 1 and 2 are set up separately and the serum sample is tested in these tubes. Conversely, if in the initial test coagulation has occurred in tube 8, tubes 9 and 10 are set up separately and the serum is tested in these tubes. For a single test this modification may seem of little value. However, when an average of five samples of serum are tested simultaneously in parallel rows of tubes as is done in our laboratory, the time and effort saved with this modification are considerable.

Interpretation of the Test—Weltmann^{3, 4} demonstrated that in the presence of an exudative or inflammatory lesion there was a shift to the left of the coagulation band and that in the presence of fibrotic lesions there was a shift to the right. Subsequent investigators have corroborated these findings.^{6, 11} However, the bulk of significant results appears to be confined to the cases in which a shift to the left was obtained. This is in agreement with our findings.

Previous writers have found the coagulation band of normal sera to be rather fixed at 6 or 7. In our hands, however, we found we had to consider the normal range as varying from 5 to 7. Wachstein¹¹ also designated a coagulation band of less than 5 as being significantly shortened, regarding a coagulation band of 5 as being suggestively shortened.

CLINICAL STUDY

In Kramer's report, his results with the Weltmann reaction as performed on about 1100 patients were summarized. The present report includes the material plus the results obtained with sera from about 1870 additional patients, a total of 3954 Weltmann tests having been performed on about 3,000 consecutive private patients.

During the period covered in this report, a Weltmann coagulation test as well as a complete blood count, urinalysis, and sedimentation rate (Westergren or Cntler) was performed at least once on each patient in addition to other indicated diagnostic procedures. Most of the patients presented gastrointestinal problems and it is in this group that we have been able to follow the results of the Weltmann reaction with the greatest degree of accuracy.

Of the 3954 Weltmann tests performed, a total of 281 showed a coagulation band of 4 or less. It was possible to closely correlate the clinical or pathological findings with the low Weltmann reactions in 237 of these cases. In the remaining 44 cases no such correlation was possible. This latter group will be discussed later.

In Table I are listed the disease entities which were associated with a significant number of shortened coagulation bands.

TABLE I

DIAGNOSIS	TOTAL NUMBER OF CASES	PERCENTAGE OF LOW WELTMANN REACTIONS
Regional ileitis	9	55.6
Diverticulitis	16	50.0
Gastric carcinoma	29	41.4
Ulcerative colitis	51	35.2
Gastric ulcer	50	32.0
Choledocholithiasis	10	20.0
Carcinoma of the colon	11	16.7
Carcinoma of the rectum	18	10.8
Cholecystitis-cholelithiasis	296	10.4
Duodenal ulcer	371	

It will be noted that in 55.6 per cent of cases of regional ileitis the Weltmann was 4 or less, this being the highest percentage in our series. In 50 per cent of cases of diverticulitis coli and in 41.4 per cent of cases of proved gastric carcinoma, the Weltmann was 4 or less. Cases of ulcerative colitis, gastric ulcer, and choledocholithiasis also showed significant percentages of low Weltmanns, 35.2, 32, and 30 per cent, respectively. Conversely, cases of duodenal ulcer, cholecystitis, and cholelithiasis showed the lowest percentages of low Weltmanns, although it has been our experience that in cases of penetrating duodenal ulcer and in ulcer with obstruction the incidence of low Weltmann reactions has been

relatively high. These results appear to confirm the finding that the coagulation band is shortened in the presence of exudative or inflammatory lesions. Ulcerative colitis is characterized by marked exudative and ulcerative inflammation. Gastric ulcer, penetrating duodenal ulcer and obstructive duodenal ulcers are generally associated with considerable inflammatory reactions and cholelithiasis is in many instances the cause of chronic low grade inflammation in the biliary tree. With regard to ulcerative colitis one might take the view that an incidence of 35.2 per cent positive Weltmanns is relatively low considering the characteristic pathology of the disease. It should be mentioned therefore that a number of the cases studied were quiescent at the time of study and have remained so.

Gastrointestinal malignancy, especially gastric malignancy, is often associated with secondary ulceration and inflammation and the latter is probably responsible for the low Weltmann rather than the malignancy per se. We have observed a number of cases which would seem to substantiate this fact. Two of the cases will be cited briefly.

CASE 5919—The patient complained of increasing constipation of one year's duration. Proctoscopy (June 6, 1946) revealed a small fungating growth six inches above the anus. The Weltmann (June 10, 1946) was 4. A barium enema (June 10, 1946) revealed a filling defect of the rectosigmoid, a chest plate made the same day showed metastatic infiltration of the right lower lobe. The primary growth was removed by abdominopерineal resection. Three months later although the pulmonary metastases had increased in size and number the Weltmann (Sept. 19, 1946) was 6. These metastases were discrete and were associated with no inflammation or exudation, a low Weltmann was not expected once the ulcerating primary lesion was removed. On Dec. 24, 1947 the patient complained of pain in the left side of the chest on inspiration. A chest plate taken that day revealed a small pleural effusion. The Weltmann performed the same day was 3.

CASE 5666—Four months after partial gastric resection for gastric carcinoma and six months after radical mastectomy for primary carcinoma of the breast the Weltmann was 5 (July 27, 1946). Four months later (Nov. 16, 1946) the Weltmann was still 5. The patient was vomiting intermittently. In January, 1947 the patient developed signs of pleural effusion which proved to be metastatic in origin. The Weltmann (Jan. 16, 1947) was 1, an expected finding because of the appearance of the exudative lesion.

DISCUSSION

The Weltmann serum coagulation reaction appears to be of sufficient value as a laboratory diagnostic aid to warrant its routine use in gastroenterological diagnosis. Admittedly it is a nonspecific reaction but this fact does not detract from its utility. In the presence of exudative or chronic inflammatory reaction the Weltmann coagulation band is shifted to the left in a significant number of instances. It has been our experience and that of others² that in general, when even there is a low Weltmann the sedimentation rate is elevated but there is no correlation between these findings. With a Weltmann of 4 one may find a sedimentation rate of 20 or 85 while in the same sedimentation rate may be noted with a Weltmann of 6 or 2. The sedimentation rate is often influenced by a number of factors many of them of relatively minor nature, and it thereby loses diagnostic significance. The Weltmann reaction however when positive

that is when 4 or less, usually indicates, in gastrointestinal complaints, an inflammatory lesion of serious import and rapidly reverts to normal when the lesion is healed or removed. It is on this account helpful in both diagnosis and prognosis. The following cases will illustrate this point.

CASE 6898—On Oct. 6, 1947, the Weltmann was 4 and the sedimentation rate, 4. Posterior wall gastric ulcer and duodenal ulcer were found on x-ray examination. Gastroscopy revealed a benign lesion. On Nov. 18, 1947, after six weeks of treatment, the patient was asymptomatic with a Weltmann of 6 and a sedimentation rate of 16. The niche was still present but much smaller.

CASE 6512—April 1, 1947, there was a history of recurrent epigastric pain of four years' duration which was relieved by food. The Weltmann was 4 and the sedimentation rate, 22. Gastrointestinal x-ray films showed no evidence of lesion but the patient was placed on an ulcer type of therapy. On May 20, 1947, there were no complaints, there was a weight gain of five pounds, the Weltmann was 7, the sedimentation rate 11. On June 17, 1947, there was occasional slight epigastric discomfort, the Weltmann was 4 and the sedimentation rate, 18. On Sept. 18, 1947, a posterior wall gastric ulcer was found on repeat x-ray study (confirmed at operation).

In 44 cases with positive Weltmanns we were unable to determine the cause of the positive reaction. Almost without exception this group consisted of patients who were seen only once and therefore an adequate diagnostic work-up and follow-up were not possible. More thorough study probably would have revealed the pathologic basis for the positive test in all or most of these patients but the possibility of false positive reactions in this group cannot be ruled out. However, in the 237 patients in whom adequate study was performed, a small number of positive tests was obtained in inflammatory states such as acute severe gingivitis, acute tonsillitis or acute sinusitis, with subsidence of the inflammation the Weltmann reactions in these instances rapidly reverted to normal. The incidence of actual false positive reactions, that is positive reaction in the absence of any demonstrable inflammatory or exudative lesion must be very slight.

It would be unwise to attribute to the Weltmann reaction values which it does not have. Many cases of serious disease of the gastrointestinal tract have been diagnosed in the presence of a normal Weltmann. However, when the Weltmann has been positive, complete diagnostic work-up has usually revealed a lesion of importance. This has led us to the clinical assumption that a patient with a low Weltmann reaction has a serious illness until absolutely proved otherwise. In a number of instances the cause of a low Weltmann has been traced to important lesions outside the gastrointestinal tract after gastrointestinal work-up had revealed a lesion sufficient to explain the presenting symptoms but not sufficient to explain the low Weltmann reactions.

SUMMARY AND CONCLUSION

The Weltmann serum coagulation test and a modification for its simplification in routine use are described.

The results of the Weltmann test as performed in over 3,000 consecutive patients and the significance of the reactions have been analyzed.

The test appears to be of considerable value in indicating the presence of exudative or inflammatory disease of the gastrointestinal tract including neoplastic lesions when the latter are accompanied by ulceration or exudation

ELECTROPHORETIC STUDY OF THE BLOOD SERUM FROM LYMPHOGRANULOMATOUS PATIENTS

ANTONIO ROTUNO, M.D., DIANA SUCHOFF, M.S., AND KURT G. STERN, PH.D.
New York, N. Y.

THE present investigation was undertaken in order to determine whether electrophoretic analysis of blood sera withdrawn from patients with Hodgkin's disease would demonstrate patterns peculiar to this disease. Such findings might be useful in diagnosis and prognosis and might throw light upon the nature of the illness. Impetus was given to our studies by recent electrophoretic investigations of human sera obtained from normal and diseased subjects indicating that the protein fraction reflected the state of the organism as a whole and that in one instance (in nephrosis) a strikingly characteristic curve was obtained.

EXPERIMENTAL

Materials and Methods.—Blood samples were withdrawn under sterile conditions from patients under observation and treatment at the Hodgkin Disease Research Clinic of St. Vincent's Hospital. These samples were allowed to clot and were stored in the refrigerator until examination*. The diagnosis of Hodgkin's disease was in every instance proved by biopsy and in some instances further confirmed by necropsy.

For electrophoretic examination 5 to 10 ml. of blood serum were diluted with two volumes of sodium barbiturate-barbituric acid buffer of an ionic strength of 0.1 and a pH of about 8.5. The diluted serum was then dialyzed in cellophane tubing against 2 liters of the same buffer for two to three days in the refrigerator. Before placing the dialyzed serum in the electrophoretic apparatus, it was centrifuged in an angle centrifuge to sediment any suspended particles; the tall section analytic cell of Tiselius-Longworth² of 11 ml. protein solution capacity was employed throughout. The apparatus was a commercial instrument closely based upon a design by Longworth.⁴ The electrophoretic diagrams were recorded photographically with the Schlicien scanning method.⁴ Visual observations in the course of the experiments were made with the Svenson-Philpot cylinder lens angular diaphragm technique.³ The temperature of the thermostat was 13° C., the voltage gradient about 6.6 v. per centimeter, and the time of electrophoresis approximately 14,000 seconds.

As light source, a mercury high-pressure burner (G. E. H-4) was used in the case of clear and little-colored serum specimens, and a single filament tungsten source (G. E. 35 A/14 T, 10 V) for the examination of colored or opalescent sera.

The hydrogen ion concentration and the conductivity of the solutions were measured with a glass electrode pH meter and an electronic conductivity bridge respectively.

This investigation was aided by a grant from the Donner Foundation to Dr. Robert Chambers and Mr. Costa Grind of the Department of Research Biology, New York University, Washington Square College.

From the Hodgkin's Disease Research Clinic, St. Vincent's Hospital, and the Department of Chemistry, Polytechnic Institute of Brooklyn.

Received for publication Oct. 17, 1947.

*The electrophoretic experiments were performed in the Institute of Polymer Research, Department of Chemistry, Polytechnic Institute of Brooklyn.

For quantitative evaluation the original photographic negatives were enlarged about three times by projection and the enlarged patterns were traced by hand. The tracings were then measured with a polar planimeter after the areas had been divided by a vertical line through the minima and subdivisions assigned to the individual components.¹ Relative concentrations in per cent were computed in terms of the ratio of these areas to that of the total area under the curve after the stationary, anomalous boundaries had been eliminated from the diagram. In the majority of cases the calculations are based on the pattern recorded from the descending boundaries but in two instances the ascending boundary patterns were also evaluated (see Tables I, II and III). It is realized that the procedure here adopted disregards the small differences in the refractive increment of the various proteins of blood serum and also the contribution of protein to the boundary anomalies. It is felt however, that in comparison with the other possible sources of error in electrophoretic determinations these factors are of only secondary importance.

The electrophoretic mobilities of the individual components appeared to be of the same order as those of normal serum hence no systematic measurements of mobilities were undertaken.

In order to avoid any bias on the part of the investigators the serum samples were submitted for examination without any clinical information. In some instances several specimens from the same patient obtained after varying intervals of time, were studied in the electrophoretic apparatus.

The sera specimens examined were obtained from twenty seven patients suffering from Hodgkin's disease eighteen men and nine women. Duration of affliction and severity of manifestations were not alike in any two cases. The age range was from 13 to 61 years and the duration range from 1 to 5 years. There were further variations, namely in the rapidity of development of disease in the state of nutrition of the patients, and so forth.

Observations and Results—A total of thirty three serum samples was examined electrophoretically under strictly comparable experimental conditions. The electrophoretic patterns obtained fell into three groups.

The first group (A) yielded diagrams somewhat similar to those of normal individuals. The albumin globulin ratio was greater than unity and the absolute as well as the relative concentrations of the individual protein components, excepting the α globulin fraction were found to be near the limits of variation found previously for normal human serum both in this laboratory and by other investigators. The electrophoretic data pertaining to this group are compiled in Table I. For the purposes of comparison the mean values as determined by Dole and Bium on the blood plasma of fifteen normal young adult male subjects under similar experimental conditions are included in Table I. The fibrinogen values are omitted because serum was used in the present study. This component amounts to approximately 5 per cent of the total area of the plasma protein pattern.

It will be noted that the values for the different serum components vary appreciably from case to case as does also the albumin globulin ratio. On the

*Relative concentration in per cent of total area as calculated from diagrams obtained in the descending limb of the cell component split in two peaks

†These values represent the average for the ascending and descending limbs of the cell. For serum these figures should be increased by about 5 per cent

whole, the albumin globulin ratios of the sera grouped together in Table I are somewhat lower and the relative concentrations of the α_2 and of the γ globulin fractions are higher than the values reported by Dole and Brun for normal serum. This is true even if allowance is made for the absence of fibrinogen in the samples studied by us. How significant these deviations are, namely how far they may be due to the fact that these sera were all obtained from patients with Hodgkin's disease, cannot be stated at this time. The same holds true for the differences in quantitative composition of the specimens examined as experiment 467 a and that withdrawn from the same patient four weeks later and examined as Experiment 467 b. A pair of electrophoretic diagrams representative of this group of sera is reproduced in Fig. 1.

Fig. 1—Electrophoretic diagram of serum from a patient with Hodgkin's disease falling into the A group (Experiment 471 Table I). normal or nearly normal pattern as to general outline absolute and relative concentration of components and electrophoretic mobility

The second group (B) of sera, listed in Table II shows the following features in common. The α globulin fraction is present in an amount which is significantly higher than in normal blood serum. The increase is limited either to the α_1 or the α_2 globulin component or it involves both of these protein fractions of high electrophoretic mobility.

With a single exception the albumin globulin ratio is below unity. In some instances the β globulin component is also increased in relative concentration (Experiments 381 382 419).

The significance of the increase in the α globulin components here observed will be discussed below in the light of the clinical findings.

Diagrams typical for this second group of sera are shown in Fig. 2.

In the third group (C) of sera examined and compiled in Table III the common denominator is a significant increase in the relative concentration of the γ globulin fraction. The albumin globulin ratio is below unity with one exception Experiment 459.

*Gamma globulin plus α component.

Fig 2—Electrophoretic diagram of serum from a patient with Hodgkins disease falling into the B group (Experiment 438 Table II) the pattern is characterized by relative decrease in albumin and corresponding increase in total globulin concentration (inverted albumin globulin ratio) as well as by strikingly enlarged alpha-1 and alpha-2 globulin areas

Fig 3—Electrophoretic diagram of serum from a patient with Hodgkins disease, falling into the C group (Experiment 460-b Table III) the pattern shows abnormally enlarged gamma globulin area in addition to increase in the alpha globulin components

Experiments 429-b and 429-c were carried out on two blood samples from the same person, an interval of four weeks ensuing between collection of samples

Diagrams of the Group C type are reproduced in Fig 3

In one instance, Experiment 368, an extra globulin component of an electrophoretic mobility intermediate between that of gamma and beta globulin

Fig 4—Electrophoretic diagram of serum from a patient with Hodgkin's disease falling into the C group (Experiment 303 Table III) in addition to the increase in gamma globulin area, characteristic for this group the pattern also shows the presence of an additional protein component, labeled x on the diagram with a mobility intermediate between β and gamma globulin. The x and gamma globulin maxima are fully resolved only in the ascending limb of the cell.

was observed (see Fig 4). This component, labelled x in the diagram was fully resolved from the γ globulin boundary only in the ascending limb of the cell.

Comparison of the tables will show that the distinction between the three groups of sera is not too sharply defined in all instances. As would be expected sera of intermediate type were encountered in this study rendering their classification difficult and somewhat arbitrary. This indicates the existence of transitions from one group to another which, perhaps reflect transitory changes in the clinical state of the patient (see below). Thus the specimen examined in Experiment 429 b might also be placed in the A group while the specimen from the same patient used in Experiment 429 c clearly falls in the C group. Other instances are the sera studied in Experiments 460 a and 460 b which show increases in the relative concentrations of the alpha as well as of the gamma globulin fractions, and those analyzed in Experiments 373 and 457.

CLINICAL FINDINGS

Group 1—The thirteen sera in Table I were obtained from eleven patients. All were ambulatory, in a good nutritional state and free from such symptoms of Hodgkin's disease as noticeable enlargement of lymph nodes. Experiments 467 a and 467 b were performed on specimens taken from the same patient

at an interval of one month, while Experiments 443-a and 443 b were done on the serum of another patient with an intervening period of four months. Since in one patient (Experiment 467-a) the disease had been manifest for only six months and in another (Experiment 422) for five years, the duration of the disease does not seem, of itself, to be responsible for the shape of the electrophoretic pattern. All patients in Group A had at one time or another received x-ray therapy, two of the patients were under x-ray treatment at the time the serum was withdrawn from them. With the exception of one patient (Experiment 422), who died ten months after his serum was examined, all patients are alive at the present time. Four of them have not required further therapy in the intervening period, their red cell sedimentation rates are normal or only slightly increased above normal value. Five other patients (Experiments 429, 457, 461, 480 and 483) have since been treated with mustard gas following enlargement of the lymph nodes, recurrence of pain, and loss of weight. In all instances the response to the treatment has been satisfactory.

Group B—In striking contrast to the sera in Group A, the ten sera falling into Group B were obtained from patients in an advanced stage of Hodgkin's disease, terminal cases actually. The patients were very ill at the time the specimens were obtained. They were bedridden and emaciated and had fever. All the patients in this group died within three days to five months after the blood samples were withdrawn for electrophoretic study.

Group C—More than one electrophoretic experiment was performed on the serum of three of these patients. Experiments 460 a and 460 b were carried out on the serum of the same patient with an interval of one month, Experiments 480-a and 480-b on the serum of another patient with an interval of two months (Experiment 480-a will be found in Table I). In a third instance of multiple analysis the first experiment fell into Group A (see Experiment 429 a, Table I), while subsequent experiments on serum samples withdrawn from the same patient after three and four months (Experiments 429 b and 429 c, respectively) were classified as Group C patterns (see Table III). Actually the diagram obtained in Experiment 429-b represents a borderline case between Group A and C sera. In neither of these patients were we able to discover a clinical basis for these variations in the electrophoretic pattern.

All of the patients in this group were ambulatory and in good nutritional state. Considered as a group, however, they represented more severe states of Hodgkin's disease than those appearing in Group A, they suffered more from fatigue (particularly patients furnishing the serum specimens for Experiments 461, 462, and 460-b). The patient represented by the sample in Experiment 368 exhibited recurrent enlargement of lymph nodes so severe as to require the institution of x-ray therapy. Two of the patients in Group C have died (Experiments 318 and 462). One other patient (Experiment 442) has been bedridden nine months and is at the present time in a terminal stage of the disease.

Attempts to correlate the electrophoretic patterns recorded in this study with individual factors, such as duration of illness, x-ray therapy, anemia, age of the patient, or sex, failed. However there is an indication that the Group B pattern prevailed in those instances in which the disease ran a rapidly fatal course. Five of the sera in this group (B) were obtained from patients who had had Hodgkin's disease less than a year, while the remaining five had been ill for about one year. This is in contrast to the patients represented by Table I, five of whom had been ill for less than a year, three for a year, three for two years, and one for three to five years. Group C shows a more general distribution as to disease duration, since two each had been ill for less than one year, for one year, and for two years and one each for three and five years.

DISCUSSION

The observations made in this study indicate that the electrophoretic pattern of the serum proteins is nonspecific for Hodgkin's disease. Thus none of the thirty-three analyses made by us produced a pattern peculiar to Hodgkin's disease. Three types of curves—designated A, B, and C—were however obtained, and each curve could be more or less correlated with the clinical state of the patient. Thus the A curve was obtained from patients whose nutritional state was and is to date, normal. The B curve, characterized by elevated alpha globulin components, was produced by terminal stage patients, those who were cachectic, anemic, febrile and edematous. Finally the C curve, characterized by elevated gamma globulins, was furnished by patients in a stage intermediate between the two others, not terminal but definitely more advanced than that of patients in Class A.

Comparison of our findings with those obtained from sera of patients with tuberculosis failed to show any parallelism between tuberculosis and Hodgkin's disease. In the former disease the alpha globulin rose early in the course of the illness, while in the latter disease a rise of the same fraction occurred terminally. In tuberculosis⁶ the increase in gamma globulin appeared to be related to immunologic processes while in Hodgkin's disease no such conclusion could be drawn.

Of further interest is the recorded increase of alpha globulin in pneumonia⁷ and in other febrile diseases which are accompanied by tissue breakdown.⁸

In the course of our studies the question arose as to whether blood sera patterns were reversible from the B and C types to A. Only one example was found, Experiment 480 b, which fell into the Group C. A repeat test on a blood sample withdrawn from this patient one month later resulted in an A curve. The maintenance of a perfect nutritional state in this patient sixteen months after the tests despite recurrence of massive lymph node enlargement would indicate a relationship between nutritional state and the electrophoretic curve rather than a relationship between lymph node enlargement and the electrophoretic serum pattern.

SPECIAL ANNOUNCEMENT

The following is inserted at the request of the Cutter Laboratories

Berkeley, Calif
May 6, 1948

For Immediate Release

Superseding our prior release dated May 5, 1948 is the following statement from Dr. R. K. Cutter, president, of Cutter Laboratories: "Contamination has been found in another and entirely different glucose solution, dextrose 10 per cent in Ringer's, according to an announcement made today by Dr. R. K. Cutter, president, of Cutter Laboratories. The company is cooperating with the Food and Drug Administration, and is requesting the assistance of health departments throughout the country, in immediately recalling from hospitals Cutter's entire line of dextrose and other solutions for mass intravenous injection. Company officials believe that discovery of this new contamination makes questionable the use of any product produced in their intravenous solutions department until this entire contamination difficulty is solved. The other products produced in this department are concentrated dextrose, distilled water, sodium citrate, normal saline solutions in 50 and 100 cc bottles, as well as all flasks supplied by Cutter for community blood and plasma banks.

"The reason for this contamination is still unknown, and until they have the positive answer, Cutter feels this is the only step that can be taken in the interest of public safety. In the meantime, arrangements are being made to supply hospitals with solutions of other manufacturers."

Cutter Laboratories.

THE TISSUE DISTRIBUTION OF RADIO ANTIMONY INHALED AS STIBINE

ROBERT E SMITH, PH D, J MURRAY STEELE MD ROBERT C EAKIN PH D
AND DEAN B COWIE AB
BETHESDA, MD

INTRODUCTION

RECENT problems in the field of tropical diseases have served to emphasize our present limitations in their treatment. To further the therapeutic use of compounds of antimony in these diseases, a better knowledge of the physiologic and pharmacologic properties of the element is necessary. New and more precise methods of assay for antimony have been recently developed which can be used for studies *in vitro* and *in vivo*.^{1, 2}

Since the toxicity of a drug is, in general, a function of both concentration and time of retention, a given agent is likely to show varying toxicities to different organ systems of the host and parasite depending upon the extent and chemical state of local accumulation and the rate at which it occurs.

Inhalation of a gaseous compound of antimony, stibine (SbH_3) has been reported effective in reducing the parasite count in chicks infected with *Plasmodium gallinaceum*.³ It therefore seemed of interest to learn the concentration of antimony as a function of time in the blood and tissues of chicks (both normal and infected with *P. gallinaceum*) and in guinea pigs after treatment with stibine containing radioantimony.

METHODS

A radioactive tracer method was selected because it permitted rapid detection and accurate measurement of amounts as small as micrograms of the element per gram of tissue without the tedious chemical manipulations of microchemical procedures. Radioactive antimony is one of the more favorable elements for this purpose, since two relatively long half life isotopes can be produced efficiently.

The antimony isotopes were prepared by the bombardment of antimony as a probe target in a sixty inch cyclotron*. The following reactions were utilized:

The two isotopes have a half life of 28 and 60 days, respectively and were used in the mixed form as produced.

Radioactive antimony was added to powdered magnesium in the ratio of 1:5 and fused in a furnace under N_2 to produce an alloy from which stibine could be generated at will by dropping a known amount of the alloy into a 50 per cent hydrochloric acid (HCl) solution in a special container†. The chamber used for exposing animals to various concentrations of the gas was designed to permit rapid withdrawal of gas samples and of exposed animals during the experiment.

Received for publication Feb. 14, 1946.

At the Department of Terrestrial Magnetism, Carnegie Institution of Washington.

†We are deeply indebted to Dr. S. H. Webster of the National Institute of Health, Bethesda, Md., for furnishing us with the basic data for this method of producing stibine.

Animals were removed from the chamber at the desired intervals, exsanguinated, and the various organs and tissues dissected and weighed immediately. Blood samples were at once centrifuged and the desired components taken up in 1 ml Luer syringes. Organs and tissues were ground with small glass mortars and pestles and the samples measured by volume in Luer syringes. Occasionally the quantity of tissue was insufficient, so that organs for several animals were pooled. The measuring cups were of Lucite and were kept free of radioactive contamination as shown by check with Geiger counters. Each cup was used only once during any given experiment. A standard volume (0.4 ml) of tissue or blood was used for measurement wherever possible. The radioactivity of the sample was measured by a beta ray counter at a standard distance. The conversion of counts per second to micrograms of antimony was made by reference to a standard sample containing a known amount of antimony, the radioactivity of which had been measured in a manner identical to that of the biologic samples.

PROCEDURES AND RESULTS

Four groups of from forty to seventy chickens (7 and 9 days old) and one set of twenty guinea pigs were gassed with stibine for a period of about fifty minutes, removed from the gassing chamber at the desired time, and sacrificed for analysis. Two groups of the chickens and the guinea pigs were from normal stock, a third group of chickens was found upon autopsy to have a respiratory infection, and the fourth had been heavily infected with *P. gallinaceum*. Parasite counts were made on each chicken in the fourth group prior to the gassing period. Stibine gas concentration for these experiments was about 25 parts per million.

Time-concentration curves were obtained for blood and certain of its fractions and for spleen, liver, kidney, heart, and brain. Each point in the curves is an average value for several individuals (two to six with the chicks, two with the guinea pigs). Some of the fluctuations observed are obviously due to sampling errors and the small number of animals used for each point. It is evident that the greatest variability occurs in muscle and, in general, the least in liver.

(Table I) There are also other potential sources of variability such as species differences and concurrent infections, but the characteristic curves of antimony concentration as a function of time are similar in comparable tissues

The whole blood curves (Figs 1 and 3) in all the experiments exhibit a high initial level which rapidly falls off, giving an exponential type of curve. One may note that the rate of disappearance of antimony from the chick blood is only about half as rapid as from the guinea pig blood

Fig 1—Antimony concentration in blood fractions of chicks infected with *P. gallinaceum*

The curves of the blood fractions are essentially similar in character to those of the whole blood (Fig 1). Although the red cell curve (Fig 1) is not corrected for packing, it is still evident that initially the antimony is largely held within the red cells rather than in the plasma; later this partition is less evident and appears to approach a value of unity.

High doses of stibine are known to produce hemolysis of the red blood cells and this occurred to some extent in these experiments. Both the direct hematocrit readings on the whole blood and the values obtained indirectly by calculations from the blood fraction levels of antimony showed a progressive fall in

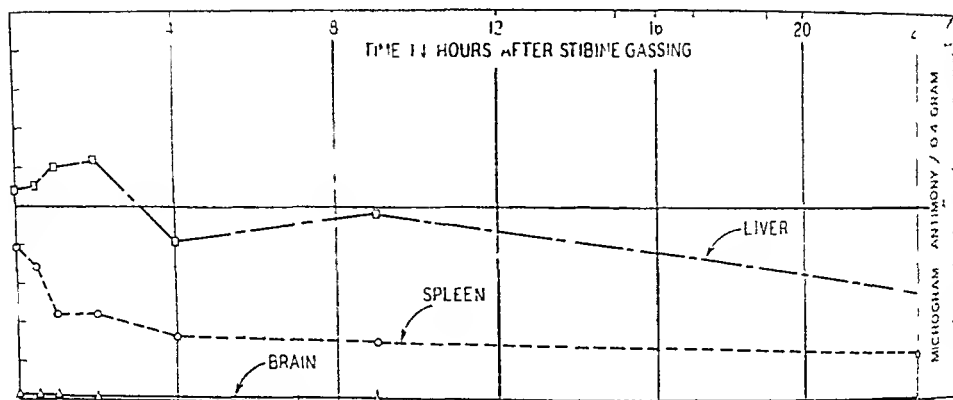

Fig 2—Antimony concentration in liver spleen and brain of chicks infected with *P. gallus*
ceum

Fig 3—Antimony concentration in blood fractions of guinea pigs following stibine gassing
(Reproduced with the permission of the Naval Medical Bulletin)

Fig 4—Antimony concentration in liver, spleen and kidney of guinea pigs following stibine gassing

Fig 5—Antimony concentration in heart and perirenal fat of guinea pigs following stibine gassing

total red cell volume during the first hour following gassing amounting to about 30 per cent. After this the hematocrit remained constant at about 20 per cent red blood cells, whether the drop was due to hemolysis or not is uncertain.

From the present experiments the elimination curves of the lung, brain, muscle, and fat tissues (Figs 2 and 5) appear similar to those of blood, and the ratio of the antimony content of these tissues to that of whole blood remains fairly constant during the course of the elimination of antimony from the body.

The concentration in other tissues follows a somewhat different curve, of which perhaps the most obvious example is that of the liver (Figs 2 and 4). The result is the appearance of a maximum concentration, reached only after an hour or more. The spleen conforms in general to this same description. The curves for heart and kidney appear to fall in between the liver type and the blood type of exchange.

Some elementary insight into the dynamics of the biologic exchange of antimony may be gained from a study of the concentration ratio of antimony in the blood to that in the various tissues at successive times after the exposure

This is illustrated by a time plot of the ratios of tissue to blood concentration for the guinea pig (Fig 6). Data from the chick experiments yielded generally similar plots. Since the ordinate is logarithmic, it is easy to read the order of magnitude of the various ratios by inspection. For example, the liver concentration at four hours is eight times, while the plasma level is approximately one fifth that of whole blood. The slopes of the curves also furnish evidence as to

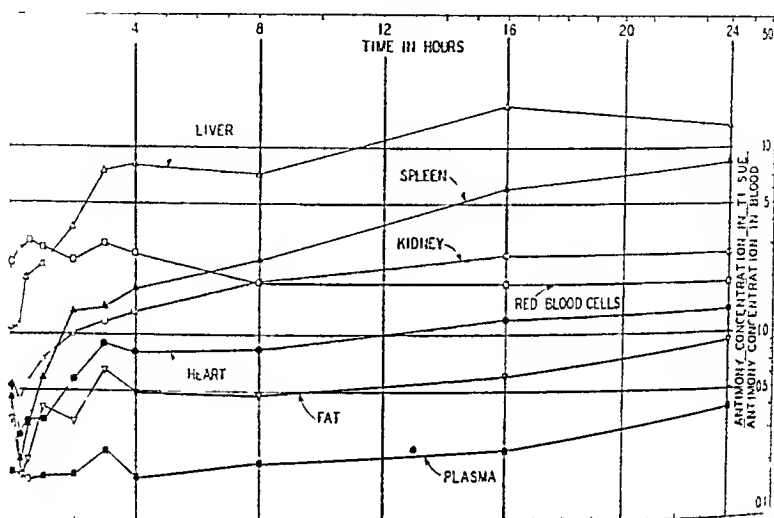

Fig 6—Ratios of antimony concentration in tissue to antimony concentration in blood (guinea pig) after stibine gassing

whether the elimination from any given organ is proceeding at a rate equal to (slope zero), greater than (slope negative), or less than (slope positive) that of the blood. For most of the data the terminal slopes appear not to depart much from zero. This is further supported by data pooled from several experiments (Table II) showing that the antimony concentrations of each of these

TABLE II AVERAGE PARTITION OF ANTIMONY BETWEEN TISSUES AND BLOOD IN CHICKS FOLLOWING TREATMENT WITH STIBINE, MEAN RATIOS (CONCENTRATION Sb IN TISSUE/CONCENTRATION Sb IN BLOOD)

*Number of experiments in which the tissue-blood ratio was measured

tissues have attained a reasonably constant proportionality to blood at least by the end of eight hours.

With the foregoing in mind and with the knowledge that the blood curves (Figs 1 and 3) exhibit a very rapid initial drop, it is clear that during the

initial period the blood is actually losing its antimony simultaneously to nearly all other tissues of the body and its observed concentration is more a function of total blood flow and relative vascularity of organs than of excretion. During the later stages the loss by excretion comprises a far greater percentage of the blood loss than is the case initially. Certainly beyond three or four hours it appears that the blood elimination becomes approximately equal to that of most of the tissues, and the concentration ratios remain essentially at constant levels characteristic for different tissues. Thus as the grand means in Table II indicate after eight hours the highest concentration of antimony is found in the liver, followed by spleen, kidney, heart and brain in decreasing order. The concentration in the first three is always greater than in the blood, that in the heart is about equal to it and in the brain it is always about 1/100 of the whole blood level. A number of other tissues such as muscle and fat resemble brain in this respect and in their apparent tendency to approximate the plasma level of antimony concentration. This constancy in the tissue blood ratios for the chick and the guinea pig may have certain therapeutic implications, since after eight hours one might estimate the probable tissue antimony concentration from that of the blood alone.

In both the guinea pig and chick experiments the concentration of antimony in the bile was measured at the various time intervals and in the guinea pig that in the urine also. The curves for bile resembled those for liver but the peak concentrations were ordinarily higher than for liver and required about twice as much time to develop. Thus the liver peak in the chicks was always reached at from one to two hours post gassing while the biliary maximum occurred at around two and one half to five hours. In the guinea pig the maximum in liver was at one half hour and in the bile at two hours. The latter coincides with the time of the urinary maximum. Since in these experiments the total output of bile and urine was not known quantitative estimates of excretion by these routes cannot be made. However some information on the excretion of antimony administered as stibine may be obtained from the curve of the summated amounts in the various organs of the body as a function of time after the end of gassing calculated from the concentration of antimony and the volume of the respective tissue. Such data yield curves which have been fitted by inspection (Fig 7) and analyzed graphically. They give empirical equations expressing the elimination as a sum of decaying exponentials and their coefficients. Having obtained these expressions for the amounts present as a function of time, one may then differentiate to obtain the rate of elimination at any particular time. Thus at the end of the gassing period the guinea pig is found to be excreting antimony at an initial hourly rate of around 60 per cent of the total amount present while the chicks are much slower ranging from 6 to 30 per cent per hour. Otherwise stated it may be said that of the initial amount of antimony present at time zero the guinea pigs had excreted 50 per cent by the end of the first forty five minutes after gassing while the chicks required from two to five hours to reach the same degree of elimination. The rough correspondence between the curve of elimination of the body as a whole

Fig. 7—Total measured antimony content of body following stibine gasping

(Fig 7) and the blood curve (Figs 1 and 3) appears to furnish additional evidence that, with stibine at least, a fair approximation to the elimination from the body may be had by recording the time curve of the blood after the first two hours have elapsed

The single experiment in which chicks heavily infected with *P gallinaceum* were gassed revealed no significant differences between these animals and the noninfected controls

SUMMARY AND CONCLUSIONS

Radioactive antimony administered as stibine gas (SbH_3) to chicks (both normal and infected with *P gallinaceum*) and to normal guinea pigs has been measured in the blood and tissues at successive time intervals following its administration. Significant differences were not apparent between distributions in normal and infected groups

The concentration of antimony in the blood stream exhibited a smoothly decaying curve, decreasing more rapidly in the guinea pig than in the chick. The red cells contained initially a much higher concentration of antimony than did the plasma although this difference was reduced with time

The concentration curves of antimony in lung, brain, muscle and fat were generally similar to those of blood, while those of the liver and to a lesser extent of the spleen, passed through a maximum about one hour following treatment. Concentration curves of the kidney and heart were of variable shape

Approximately four hours after treatment the tissue antimony levels became constant with respect to order of rank: those in the liver, spleen and kidneys were greater than in whole blood; all other tissues showed concentrations less than the blood but as much as or more than the plasma

Evidence is adduced to show that the rate of elimination from the body is higher for the guinea pig than for the chick

In addition to the many who so generously assisted in the work from time to time, we wish to acknowledge with particular gratitude the assistance of I. H. Gordon, PhM2, V6 USNR, Roy L. Evans, PhM2, V6 USNR, F. N. Cille, PhM2, V6 USNR and C. J. Spear, PhM1, V6, USNR

LABORATORY METHODS

A SIMPLE BEDSIDE METHOD FOR THE ESTIMATION OF BLOOD SUGAR

RACHEL S LEECH, A B, AND NORMA WOODFORD, B S
BOSTON, MASS

THE reaction between glucose and dinitrosalicylic acid for the estimation of glucose was first used by Sumner in 1921¹. Since then, the Sumner reagent has been in general use for the measurement of urine glucose and recently has been adapted for the determination of blood glucose on a tungstic acid filtrate.²

The following procedure is an extremely simple method for the approximate determination of blood sugar on a zinc hydroxide filtrate using the Sumner reagent as modified by Epton.³ The method, although adaptable within certain limits for a strictly quantitative procedure, as discussed later, is primarily designed for an approximate estimation of blood sugar by the physician or nurse with a minimum of time and equipment and limited laboratory facilities. As shown in Table I, the approximate results obtained in five minutes using the color standards or color chart described here are essential checks with determinations as carried out by the Folin-Wu⁴ micromethod and the Folin Malmros or the rapid Hagedorn-Halstrom-Jensen⁵ micromethods.

REAGENTS

(A) 10 Per cent zinc sulfate ($\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$)

(B) 0.5 N Sodium hydroxide (A stock solution preferably is kept in a paraffined bottle.)

These solutions, A and B, are the regularly employed macrosolutions for preparing a Somogyi blood filtrate.⁷ They may be conveniently kept in small bottles provided with dropping pipettes graduated to deliver 0.4 ml of solution. Stock bottles, tightly stoppered, keep well over a period of months.

(C) A solution of dinitrosalicylic acid prepared as follows:⁸

(1) A sodium potassium phenol stock solution is made by dissolving 400 Gm of Rochelle salts (sodium potassium tartrate) in about 600 ml of warm distilled water and adding 13 Gm of phenol crystals. The Rochelle salts and the phenol are dissolved and mixed well, and the solution is then diluted to a volume of 1,000 milliliters.

(2) 12 Gm of monosodium 3,5 dinitrosalicylate* are dissolved in 700 ml of distilled water heated to a temperature of 65° C. When dissolved, the entire volume is poured into the liter of sodium-potassium phenol stock solution and mixed well. A yellow precipitate forms.

From the George F. Baker Clinic, Elliott P. Joslin, M.D., Medical Director, New England Deaconess Hospital.

Received for publication Nov. 13, 1947.

*Eastman Kodak Company, Rochester, N. Y.

(3) 6 Gm of sodium bisulfite (NaHSO_3) are added to the solution (2) and the whole is thoroughly mixed

(4) Finally, 300 ml of 10 per cent sodium hydroxide (25 N) are added and the final solution is completely mixed. The yellow precipitate formed in step 2 disappears at this point. The solution should be put in a brown bottle and allowed to stand for about one week before using.

To test the solution titrate 5 ml with normal acetic acid to the appearance of a white precipitate. If the reagent has been correctly prepared 1.86 ml of the acid should be required for 5 ml of the reagent. This solution, if kept in the dark in a brown bottle, is stable for at least four to five months. If any cloudiness develops, the solution should be filtered before use.

APPARATUS

(A) A test tube approximately 12.5 cm long and 15 mm in diameter graduated at 3.8 ml, Tube 1

(B) A Pyrex test tube approximately 15 cm long and 15 mm in diameter, graduated at 2.0 and 4.0 ml, Tube 2

(C) A eup or beaker in which a small amount of water may be boiled

(D) A small funnel fitted with a piece of folded filter paper (Whatman No. 1, 5.5 or 7.0 cm in diameter)

(E) A micro blood pipette graduated at 0.1 and 0.2 milliliter

(F) A prepared color chart or a series of color standards

PROCEDURE

Measure into Tube 1, 0.4 ml each of Reagents A and B using the calibrated droppers with which the bottles are equipped. Add distilled water to the 3.8 ml mark. In all quantitative measuring it should be remembered always to use just sufficient liquid to make the bottom of the meniscus on a line with the mark calibrated for the desired amount. Rotate the tube gently and introduce into the precipitating mixture exactly 0.2 ml blood taken directly from the ear or finger by means of a micro blood pipette. (Venous blood may be used if collected with fluoride oxalate* as a preservative and anticoagulant.) Mix the contents of the tube with the pipette by alternately sucking up and blowing out the blood mixture then filter immediately into Tube 2 by means of the small funnel and filter paper. A water clear filtrate should result†. Allow the filtrate to collect exactly to the 2 ml mark. We have found that by using the technique described with Whatman No. 1 filter paper 5.5 or 7.0 cm in diameter 2 ml of filtrate may be secured easily and rapidly. Add Reagent C to the 4 ml mark. Mix thoroughly by rotation and immerse in a boiling water bath for exactly three minutes. The color changes during the heating period from a pure yellow to

*The fluoride oxalate is prepared by thoroughly mixing together 0.0 Gm powdered sodium fluoride and 0.0 Gm powdered potassium oxalate. Seventy milligrams of the mixture are used for each 5 ml of blood.

†Although for complete precipitation of protein a freshly precipitated zinc hydroxide solution is not usually recommended unless heat is used we have found that the double concentration of reagents yields a very clear filtrate which gives an essentially negative biuret reaction.

*Comparison made with color chart alone

†Different capillary blood samples obtained simultaneously from the ear

a deeper yellow, yellow brown, or reddish brown depending on the concentration of glucose present. Cool slightly after removal from the water bath and compare the color obtained with the color chart or standard tubes, matching it to the nearest color. Shades between standards can be approximated. Table I gives the results obtained on sixty blood samples using the described rapid estimation in comparison with other standard methods. In each case the rapid approximation was done either before the accurate determinations or was done by a second individual who had no knowledge of the correct results obtained with standard procedures.

PREPARATION OF COLOR STANDARDS

A series of accurate color standards may be prepared as outlined below. If prepared under the conditions given these standards are accurate to within 5 per cent for a period of at least one month if kept in the refrigerator (40° F.) when not in use.

An accurate stock glucose solution prepared in saturated benzoic acid containing 0.2 Gm glucose per 100 ml is required. This solution is permanently stable if kept free from contamination. A dilute standard containing 10 ml of this stock diluted to 100 ml with distilled water is used in preparing the standard tubes as follows.

TABLE II CHART FOR PREPARATION OF GLUCOSE STANDARDS

DILUTE GLUCOSE STANDARD (ML)	BOILED WATER (ML)	BLOOD SUGAR EQUIVALENT (MG PER 100 ML)
0.5	3.5	50
1.0	3.0	100
1.5	2.5	150
2.0	2.0	200
2.5	1.5	250
3.0	1.0	300

A series of tubes using quantities of the *dilute* glucose standard in increasing amounts of 0.5 ml from 0.5 to 2.5 or 3 ml is prepared. Freshly boiled distilled water which has been cooled is added in amounts to make a total volume of 4 milliliters. Then to each tube exactly 4 ml of Reagent C are added, the contents of the tubes are mixed and the tubes placed in a boiling water bath for three minutes as outlined under Procedure for blood. After cooling 4 ml of the colored solutions are transferred to clean, dry tubes of the same diameter as those in which the determination is to be made. Two drops of toluol are added to each tube and the tubes stoppered and sealed with paraffin and labeled with the proper value in milligrams per 100 ml of blood.

The series of standards which we have used is given in Table II. Standards between these values may be prepared but are not necessary. It is advisable however to prepare a new series of standard tubes with every new lot of Reagent C as slight variations may occur.

Although the series of color standards may be preferable a color chart from these standards may be prepared with ordinary paints. With a little experience good approximations can be made with the color chart (Table I). It was not feasible to reproduce here the color charts made and used by us.

DISCUSSION

The validity of the foregoing procedure as a rapid method for the estimation of blood sugar is apparent from the results given in Table I. Certain points regarding the method, however, should be noted. The reduction of the Summer reagent, under the conditions outlined, is directly proportional to the concentration of glucose present between the equivalent of a blood sugar of 75 mg and 300 mg per cent, Fig 1.

Fig 1—Two typical curves obtained from two series of standard glucose solutions using different lots of Reagent C. Curve A was done July 17, curve B December 15. The readings were taken on a Leitz photoelectric colorimeter using the green filter No. 401 and plotted against the glucose concentration expressed as milligrams of blood sugar per 100 milliliter.

The curves given in Fig 1 were obtained with standard glucose solutions using a Leitz photoelectric colorimeter with the green filter, Leitz No. 401. Slight variations occur, as indicated by these two typical curves, with different lots of Reagent C. It is essential, therefore, if the color of an unknown is to be measured accurately on a previously standardized photoelectric colorimeter, that the instrument be restandardized with each new lot of Reagent C. Although quantitative technique throughout the procedure would obviously be desirable if the final measurement of color was exact, our results do not warrant such an assumption as a necessity. With accurately calibrated tubes and reasonably careful technique, any error due to lack of quantitative pipetting is not of clinical significance, Table III.

In the procedure as recommended the precipitation of blood protein is effected by means of freshly precipitated zinc hydroxide. The concentration of zinc sulfate and sodium hydroxide used is sufficient to yield a protein free filtrate without the use of heat*. The filtration is rapid and the necessary volume of filtrate is quickly and easily obtained. A second procedure for precipitation of the protein may be used if desired. The blood may be pipetted directly into 3 ml of water the pipette being rinsed thoroughly by alternate sucking up and blowing out of the water solution. To the blood and water solution then the necessary quantities of Reagents A and B are added the tube is stoppered and the contents are mixed by shaking well. Using this method for precipitation of the protein filtration is less rapid and the total volume of filtrate is slightly less. If this method of precipitation is adopted, it is recommended that tubes graduated at 1.5 and 3.0 ml be used rather than at 2.0 and 4.0 milliliters.

*Blood introduced into Zn(OH)₂

†Blood introduced into water then ZnSO₄ solution (Reagent A) added followed by NaOH solution (Reagent B)

This method for precipitation of the protein offers the advantage of not getting the protein precipitate in the micropipette thus making the cleaning of the pipette considerably easier. Furthermore this method for precipitation of the protein yields a true Somogyi filtrate and in some instances the blood sugar values obtained may be appreciably lower (Table IV) approaching probably the true blood sugar value.

Since in its simplest form the method is dependent for the final estimation on a color comparison with standard tubes or a color chart the importance of

standardizing one's individual technique for judging the color cannot be overemphasized. If standard tubes are used, the unknown solution should be in the same size tube as the standards. In using the standard tubes, we have obtained the best results by holding the unknown tube between the two closest standards and judging the light which comes through the tubes. In this way the density of the color can be fairly accurately approximated. If a color chart is used, we have obtained the best results by holding the tube containing the unknown obliquely above the block of color nearest in shade, with the source of light coming toward the tube from behind the worker. We have used daylight for all of our comparisons.

The determination is designed for 0.2 ml of blood. When a blood sugar value over 300 mg per cent is found, greater accuracy can be obtained by repeating the determination using 0.1 ml of blood and subsequently multiplying the result by two. In this way, comparison is made with a standard under 300 mg rather than by an attempt at a comparison with the very deep red brown colors obtained with a 400 or 500 mg standard.

The method in its present form is not suitable for the estimation of very low blood sugar values. Between 50 and 75 mg per cent, fairly good approximations can be made. Below 50 mg per cent the color of the reagent blank is so intense that any increase of color due to glucose is indiscernible.

SUMMARY

A simple method designed for the rapid estimation of blood sugar by the physician or worker with a minimum of laboratory experience and equipment has been described. The method is based on the reduction by glucose of dinitrosalicylic acid and closely checks determinations done by other standard methods.

PRODUCTION OF TEMPORARY DIABETES MELLITUS IN MAN WITH PITUITARY ADRENOCORTICOTROPIC HORMONE RELATION TO URIC ACID METABOLISM

JEROME W. CONY, M.D. LAWRENCE H. LOUIS, S.C.D. AND
CLAYTON E. WHFELE, M.D.
ANN ARBOR, MICH.

THE production in normal animals of either temporary or permanent diabetes by the injection of crude saline extracts of anterior pituitary gland has been amply demonstrated^{1, 2} and repeatedly confirmed.⁴ The factor or factors responsible for the diabetogenic activity of these extracts remain unknown. Using biologically pure growth hormone, Marx, Anderson, Fong, and Evans reported an increase in glycosuria of partially depancreatized rats. Ingle, Li, and Evans⁵ used 7 mg. per day of pure adrenocorticotrophic hormone (A.C.T.H.) in normal rats force fed a high carbohydrate diet and they observed increased urinary nitrogen, glycosuria and hyperglycemia during the period of administration. Bennett and Li⁷ produced marked increase in glycosuria and severe nitrogen loss in alloxan diabetic rats with the use of pure adrenocorticotrophic hormone. When they used pure growth hormone in such preparations they observed only an occasional increase in glycosuria. It is significant that this occurred even in the presence of the nitrogen retention which characterizes the activity of growth hormone. Thus so far as pure pituitary fractions are concerned, adrenocorticotrophic hormone has been found to have the greatest diabetogenic effect of any tested to date. Since it is known too that administration of suitable amounts of C11 or C11-17 oxysteroids to rats is diabetogenic,^{8, 10} the assumption is valid that the diabetogenic activity of adrenocorticotrophic hormone is due to cortical elaboration of large amounts of C11 and C11-17 oxysteroids among other possibilities.

In man neither a diabetogenic nor an anti-insulin effect of administered corticosteroids has been demonstrated^{11, 12} with doses as high as 100 mg. per day of 11-dehydrocorticosterone. This may be the result of too small a dose if the estimation of Ingle and co-workers⁵ of the secretory potentiality of the adrenal gland is valid.

The administration of purified adrenocorticotrophic hormone to man has been limited by the difficulties attending its preparation. It was used first in two normal men by Browne.¹³ No spontaneous glycosuria was observed in either subject. One who had received 40 mg. per day for two days showed a decrease in carbohydrate tolerance on the morning of the third day and glycosuria was noted during the glucose tolerance test (100 Gm. orally). Thirty

Received for publication April 17, 1948.

minutes before the test the subject had received 40 mg of adrenocorticotrophic hormone subcutaneously. In two recent reports of experiments in which larger doses were given, no glycosuria was observed. Mason and co-workers,¹⁴ employing doses as high as 100 mg per day (eight injection days over a twelve day period) of adrenocorticotrophic hormone (prepared according to the method of Li, Evans, and Simpson¹⁵), found no impairment of carbohydrate tolerance but observed a mild increase in resistance to insulin. Foisham and co-workers¹ using 40 mg per day of adrenocorticotrophic hormone, prepared by a modification of the method of Sayers and associates,¹⁷ for six days, noted a small rise of the fasting blood sugar level in their normal subject. No glycosuria occurred. Glucose tolerance tests were not reported.

The present report deals with the production of a diabetic state in all of three normal subjects who received daily injections of purified adrenocorticotrophic hormone. This state was characterized by glycosuria and a significant loss of carbohydrate tolerance during the entire period of adrenocorticotrophic hormone administration. In two of these subjects, one man and one woman, the loss of tolerance for carbohydrate was great. These subjects exhibited severe negative nitrogen balance during the period of adrenocorticotrophic hormone injection. The third subject, a woman, developed a mild glycosuria, lost much less tolerance for carbohydrate, and demonstrated no negativity in the nitrogen balance study. In fact, glycosuria developed during a period of nitrogen retention.

METHOD OF STUDY

Procedure—Two apparently normal, 24 year old, female senior medical students (subjects A M and M W) were fed a constant, carefully weighed diet for thirty two consecutive days. The diet contained 99 Gm of protein, 300 Gm of carbohydrate, and 176 Gm of fat. Analysis showed nitrogen, 15.75 Gm, sodium, 4.40 Gm, and potassium, 4.8 grams.

The first twelve days established a reliable base line. During the next eight days each subject received 120 mg of adrenocorticotrophic hormone (Batch 37 K E, Table I) intramuscularly daily. The total amount was given in three doses (40 mg every eight hours). The remaining twelve days were used to study recovery from the abnormal metabolism induced.

The third normal subject, a 37 year old dental student (Subject R S), was fed a constant diet for thirty three days. It contained 99 Gm of protein, 300 Gm of carbohydrate and 197 Gm of fat. Analysis showed nitrogen, 15.75 Gm, sodium, 4.63 Gm, and potassium, 4.86 grams. After a ten day base line period the subject was given 50 mg of adrenocorticotrophic hormone every eight hours (150 mg per day) intramuscularly daily for the next ten days. This material was from Batch 37 K G (Table I). During the last thirteen days the recovery phase was studied.

Pituitary Adrenocorticotrophic Hormone—The materials used in this study were prepared by a modification of the method of Sayers and co-workers¹⁴. The laboratory has applied us with the properties of these materials (Table I). In all cases the adrenocorticotrophic hormone was given in a concentration of 10 mg per 1 cc of saline.

Chemical Methods—Determinations performed, which are connected with this report, were blood sugar,¹⁸ blood uric acid,¹⁹ blood glutathione,² urinary uric acid,¹ and urinary glucose.²² All nitrogen determinations were done by the macrokjeldahl method. Glucose tolerance tests performed during the period of adrenocorticotrophic hormone administration were begun at 8 A M, nine hours after the last injection of adrenocorticotrophic hormone.

*We are indebted to Dr J R Mote, The Armour Laboratories, Chicago III for the purified adrenocorticotrophic hormone used in these studies.
†In the Armour Laboratories, Chicago III.

order to avoid any immediate or extraneous glycogenolytic effect which could be assigned to the adrenocorticotrophic material used. On such days the dose of adrenocorticotrophic hormone usually given at 7 A.M. was given at the conclusion of the test (noon). The glucose was administered orally on the basis of 1.75 Gm per kilogram of base line body weight, and the same total amount was given for all subsequent tests (Subject M W, 108 Gm., Subject A M, 104 Gm., Subject R S, 122 Gm.)

TABLE I PROPERTIES OF THE ADRENOCORTICOTROPIC HORMONE PREPARATIONS EMPLOYED

BATCH	A O T H ACTIVITY (PER CENT OF ARMOUR STANDARD*)	PRESSOR ACTIVITY— ROOSTER D P (UNITS/MG)	OXYTOIC ACTIVITY— GUINEA PIG UTERINE STIP (UNITS/MG)	PROLACTIN ACTIVITY— PIGEON CORP SAC (UNITS/MO)	GONADOTROPIC ACTIVITY— COLLIP (UNITS/MO)	SOLUBILITY
7 K E	41.5 ± 12	0.005	0.0015	0.5	2.0	Soluble in saline
17 K G	34.8 ± 2	0.066	0.017	0.5	2.0	Soluble in saline

The biologic activity of Armour A O T H Standard (LA 1 A) is such that a single intravenous injection of 0.004 mg produces consistently a 0 to 30 per cent decrease in adrenal ascorbic acid content of the hypophysectomized rat.

RESULTS AND COMMENTS

No immediate symptomatic effects of injections of adrenocorticotrophic hormone were experienced by any of the subjects. This is different from the experience of Forsham and co-workers¹ who used different batches of Armour's purified adrenocorticotrophic hormone and observed symptoms suggesting posterior pituitary pressor and oxytocic activities. Subject M W developed redness and itching at the site of injections during the last three days of administration (Days 6, 7, and 8). More annoying to her at this time was the itching and discomfort which occurred at sites of prior injections. Subject R S developed severe acne of the face, scalp, shoulders, back, chest and abdomen on the eighth day of injection. He had never had acne. This began to regress slowly upon cessation of injections (eleventh day) but persisted with continued regression for four weeks. Both female subjects experienced gross irregularity of the menstrual cycle which followed the adrenocorticotrophic hormone injection period. The next cycle returned to normal. It should be mentioned that in all three subjects there occurred a four to fivefold increase over the base line of the daily total excretion of 17 ketosteroids.³ This is a much greater increase than has been observed previously^{13,1} but the amounts of adrenocorticotrophic hormone employed in our experiments were greater than those previously used. A great retention of sodium and a diuresis of potassium were also observed in all subjects.²³

Table II and Fig 1 demonstrate the data bearing on carbohydrate metabolism which were obtained on Subject R S. This subject showed the most striking disturbance of sugar metabolism of all three subjects given adrenocorticotrophic hormone. During the ten day adrenocorticotrophic hormone period a total of 252 Gm of glucose was excreted in the urine, 12 Gm appearing on the first day and 36 and 33 Gm, respectively, on each of the last two days. During the same period, urinary nitrogen averaged 19.3 Gm per day as compared with an

average of 13.5 Gm per day observed in the base line period. A total of 363 Gm of extra nitrogen was excreted in the urine in the adrenocorticotrophic hormone period. This represents loss of 360 Gm of body protein in ten days, or 36 Gm per day, despite a daily intake of 99 Gm of protein. Negative nitrogen balance continued for ten days after cessation of adrenocorticotrophic hormone and amounted to an additional loss of 119 Gm of body protein.

If, for the adrenocorticotrophic hormone period, one assumes that all of the excreted glucose had arisen by excessive glycconeogenesis from protein, one arrives at a D/N ratio of 4.3 and a glucose from protein conversion rate of 70 per cent. That such an assumption is not justified under the conditions of this

Fig 1

study is obvious. There is no reason to believe that the subject could not have disposed of an additional 100 or more grams of glucose (over and above the 300 Gm contained in his diet) normally and without glycosuria had he not been receiving adrenocorticotrophic hormone. To assume, then, that glucose derived from body protein so taxes the normal mechanisms by which glucose is utilized that those mechanisms break down is unreasonable, and especially so when one realizes that an average of 36 Gm of sugar per day is the maximal amount that could have been derived from protein, in Subject R. S., had 100 per cent conversion been possible. Thus it becomes clear that regardless of the source of the glucose (dietary carbohydrate and protein, and endogenous protein), there has occurred a very important over-all decrease in the capacity of the subject

 A Method of Benedict and Franke² B method of Buchanan and co worker¹¹

to dispose of glucose normally (by oxidation and/or conversion to fat) This contention is supported by the facts that not only has nonutilized glucose appeared in the urine but, in addition more unutilized glucose has accumulated in the body fluids (see Table II Fasting Blood Sugar Levels) the liver,¹ and very likely in the muscles as well Further that this state of affairs (decreased capacity to utilize glucose) is related not to negative nitrogen balance but to the presence of adrenocorticotrophic hormone activity is evident (compare Days 11 and 12 with Days 21 and 22) Finally the glucose tolerance curves (Fig 1) demonstrate a greatly decreased capacity to clear the blood of absorbing glucose This deficiency is apparent after one day of adrenocorticotrophic hormone administration After eight days of adrenocorticotrophic hormone there can be little question that a diabetic state is present

In the light of present knowledge two main possibilities exist by which one might explain the decreased capacity of the tissues to dispose of glucose

(1) Interference with the peripheral activity of insulin due to (a) increased hexokinase inhibition by corticosteroids or by adrenocorticotrophic hormone, (b) stimulation of pancreatic alpha cell secretion²⁴ by either adrenocorticotrophic hormone or adrenaal corticosteroids, and/or (c) destruction of insulin peripherally

(2) Diminution in the production and/or release of insulin from the beta cells of the pancreatic islets

No attempt was made to study the first possibility. The second one was studied with respect to uric acid metabolism and the blood levels of glutathione (Table I)

The administration of adrenocorticotrophic hormone produces a large increase in the urinary excretion of uric acid accompanied by a decrease of blood uric acid. It is believed by some¹⁵ that neither increased blood clearance for uric acid nor hemodilution can adequately explain these phenomena and that increased production of uric acid probably accounts for the increased excretion. It is conceivable that during the increased production of uric acid which occurs as the result of administration adrenocorticotrophic hormone (and which is induced by the elaboration of excessive amounts of 11 and 11-17 oxygenated cortical steroids), intermediaries, similar in their effects to alloxan are produced and reach a critical intracellular concentration in the beta cells. Such a concept need not imply necrosis of beta cells, as is known to occur after the administration of large amounts of alloxan, but could suggest depression of intracellular enzymatic production of insulin as the result of prolonged exposure to relatively lower concentrations of noxious intermediaries of uric acid metabolism.

It is appreciated that such considerations must be regarded as speculative at present. But in Table I are recorded data related to the problem. Note that the lowest levels for blood glutathione were obtained during the adrenocorticotrophic hormone period (determinations of glutathione were not done in the other two subjects). Note, too, that the highest levels of urinary uric acid were obtained during the same period. It is well known that administration of alloxan to animals produces a prompt and severe depression of the level of blood glutathione²⁵. The recent report of Griffiths²⁶ showing the production of hyperglycemia in rabbits by first lowering blood glutathione by means of a diet deficient in cystine and methionine and then administering uric acid intraperitoneally suggests a possible relationship of those experiments to the ones here reported.

The results of the studies of carbohydrate metabolism in the other two adrenocorticotrophic hormone treated subjects are shown in Table III and Figures 2 and 3. Subject A. M., while ingesting 99 Gm of protein daily, destroyed, in addition, 113 Gm of body protein during the eight-day adrenocorticotrophic hormone period, an average of 14 Gm per day. A total of 30 Gm of glucose appeared in the urine over the same interval. From the fasting blood sugar level and the daily glycosuria (Table III) it appears that in this subject the me-

Day of glucose tolerance test (see Figs 2 and 3)

intense depression of carbohydrate utilization occurred during the first three days of adrenocorticotrophic hormone administration. This was a period when nitrogen balance was being maintained. Unfortunately a glucose tolerance test was not done during this period. The period of negative nitrogen balance began on the fourth day of injections of adrenocorticotrophic hormone. Thus again we note the absence of a clear temporal correlation between nitrogen loss and the disturbance of carbohydrate metabolism. It is clear that in both subjects so far discussed (Subjects R S and A M) negative nitrogen balance and glycosuria were provoked by administration of adrenocorticotrophic hormone but it seems unlikely that either was dependent upon the other. Fig 2 shows that after seven days of injections a diabetic curve was obtained in Subject A M.

Subject M W showed the mildest effect of adrenocorticotrophic hormone upon carbohydrate metabolism of any of the three subjects studied (Table III and Fig 3) although she was treated on the same days and by the same procedures as those which apply to Subject A M. Variations among individuals and species differences in the response to adrenocorticotrophic hormone may account, in part, for the discordant results so far reported.

Fig. 2

Fig. 3

Table III shows that Subject M W exhibited glycosuria during the entire eight days of adrenocorticotrophic hormone administration. It is noteworthy that negative nitrogen balance was not produced in this subject at any time. In fact, the initial response was that of nitrogen retention. The sharp increase in urinary excretion of uric acid however was almost identical in absolute values, with that obtained for Subject A M. In all three subjects during the adrenocorticotrophic hormone periods the glycosuria shows a much closer correlation with the increased production of uric acid than with the state of nitrogen equilibrium.

Table III demonstrates another interesting finding. In both subjects glycosuria continued for one day after cessation of adrenocorticotrophic hormone administration and then ceased for forty eight hours. During this period urinary uric acid levels fell to the base line values. Fasting blood sugar determined on the morning of the third postinjection day was abnormally low for both subjects. On the following day glycosuria reappeared accompanied by a great increase in the urinary excretion of uric acid. These findings suggest that the following sequence of events occurred: (1) exogenous adrenocorticotrophic hormone depressed production of endogenous adrenocorticotrophic hormone; (2) cessation of exogenous adrenocorticotrophic hormone administration resulted in a short period of hypopituitarism with respect to adrenocorticotrophic hormone (in these subjects about forty eight hours); (3) this situation was at once reflected as hypoadrenocorticism (this interpretation is supported not only by the low levels of fasting blood sugar but also by the tremendous changes in electrolyte metabolism and in urinary steroid excretion which occurred during this same interval²²), and (4) an intense stimulus finally evoked pituitary adrenal activity again. This rebound in pituitary activity from a dormant state releases a greater amount of corticoids than are needed and produces spontaneously the same metabolic changes in somewhat smaller degree that are observed on the first day of administration of exogenous adrenocorticotrophic hormone (Table III). It should be noted again that the spontaneous reappearance of glycosuria is related in time to the increased uric acid excretion rather than to changes in nitrogen metabolism.

SUMMARY

Three normal young adults were given 120 to 150 mg. of purified pituitary adrenocorticotrophic hormone intramuscularly daily in divided doses for eight to ten consecutive days. On the first day all subjects developed glycosuria which continued throughout the entire period of adrenocorticotrophic hormone administration. The glycosuria averaged 25.2, 3.8 and 2.5 Gm. per day for the respective subjects. Two of the subjects lost large amounts of body protein during the period of adrenocorticotrophic hormone injection despite an adequate protein intake. Significant negative nitrogen balance continued for five to six days following cessation of adrenocorticotrophic hormone administration but glycosuria ceased within twenty four hours of the last injection. Both of these subjects developed hyperglycemic plateau glucose tolerance curves during the adrenocorticotrophic hormone period. Normal carbohydrate tolerance

returned within one to two weeks after adrenocorticotrophic hormone was stopped

The third subject exhibited no loss of body protein. Nevertheless, glycosuria persisted during administration of adrenocorticotrophic hormone. Total glycosuria and loss of carbohydrate tolerance were less in this subject than in the other two.

Analysis of the data indicates that although greater loss of carbohydrate tolerance occurred in the two subjects who exhibited marked negative nitrogen balance, the glycosuria was not related either in time or in degree to the loss of body protein.

The data indicate, furthermore, that the loss of carbohydrate tolerance produced by adrenocorticotrophic hormone is the result of a depressed capacity of the tissues to utilize glucose (by oxidation and/or conversion to fat).

A close temporal correlation was observed in all three subjects between loss of carbohydrate tolerance and increased urinary excretion of uric acid during the periods of administration of adrenocorticotrophic hormone. Two subjects showed a spontaneous return of glycosuria on the fourth day after adrenocorticotrophic hormone had been stopped. In each case this was associated with a sharp increase of urinary uric acid. The temporary return of glycosuria and heightened uric acid excretion in the postadrenocorticotrophic hormone period was due to acute elaboration of endogenous adrenocorticotrophic hormone following a prolonged period of depressed productivity of endogenous adrenocorticotrophic hormone caused by administration of the exogenous hormone.

Observations made on one subject suggest the possibility that a heightened intracellular production of uric acid and its intermediaries produced by adrenocorticotrophic hormone, together with a fall of the levels of glutathione and perhaps other sulfhydryl-bearing substances, may diminish enzymatic production or release of pancreatic insulin. Such a mechanism could explain the close correlation between uric acid metabolism and carbohydrate metabolism which our data indicate.

We wish to thank Dr. William D. Robinson and Dr. Walter D. Block of the Arthritis Research Unit, University Hospital, for the determinations of urinary uric acid by the method of Buchanan, Block, and Christman.

A COMPARATIVE STUDY OF THE SERUM ALBUMIN GLOBULIN RATIO, THE CEPHALIN-CHOLESTEROL FLOCCULATION, AND THE THYMOL TURBIDITY TESTS FOR LIVER FUNCTION

ANDRE C KIBRICK, PH D, AND ALFRED B CLEMENTS, MD
BRONX, N Y

THE derangement in the formation of serum proteins which takes place in certain diseases of the liver may now be described quantitatively by determining the relative amounts of the protein fractions that are separated electrophoretically in the Tiselius apparatus¹. An analysis of normal human serum having a total protein content of about 7.5 Gm per 100 ml shows 60 to 65 per cent in the albumin fraction and about 10 per cent in each of the α , β , and γ globulin fractions. In the serum of patients with liver disease the total protein content may be normal, but the proportions of the different fractions are usually changed. There is often a decrease in the albumin fraction and an increase in either or both of the β and γ globulin fractions. Heretofore the albumin globulin ratio of serum has been determined chemically by fractionation with high concentrations of salt to precipitate the globulins according to various methods,² and quite consistent results are possible when the procedures are carefully standardized. However, salt fractionation methods have fallen into some disrepute due to the difficulty of obtaining good duplicate values when all the factors involved are not properly controlled. Furthermore, recent studies have demonstrated that the values of the albumin-globulin ratio obtained by carefully fractionating the proteins of serum with salt do not reflect the actual partition of the electrophoretic patterns.³ In 1945, Pillemer and Hutchinson reported a simple chemical method for the fractionation of the albumin and globulin of human serum by methyl alcohol in the cold which agrees quite well with the results of electrophoresis.⁴ This method should prove useful in many laboratories since the Tiselius apparatus is elaborate and expensive and since the electrophoretic method at present does not seem to be adapted to general routine use.

Many tests for liver function have been devised which are based on the derangement in the formation of the serum proteins. Until recently these were only vaguely understood and their value was determined empirically from the agreement of the results with clinical findings. At present, two of these tests are widely used. The cephalin-cholesterol flocculation test of Hanger⁵ measures the degree of precipitation twenty-four and forty-eight hours following the mixture of serum with an antigen emulsion prepared from sheep brain cephalin and cholesterol. The thymol turbidity test,⁶ which was modified for quantitative photoelectric estimation by Shank and Hoagland,⁷ measures the turbidity produced by adding serum to a buffered thymol solution. Many workers have

From the Departments of Pathology and Internal Medicine The Bronx Hospital
Received for publication Nov. 22, 1947

compared the results of the two tests in liver disease⁸ and it appears likely that they are not a measure of the same abnormality since in many instances the results do not agree. The mechanism of the cephalin cholesterol flocculation test has now been clarified by Moore and co workers with the aid of electrophoretic studies.⁹ Two factors seem to be involved in a positive reaction. One is in the γ globulin fraction and the other is a reduction of the inhibition by albumin. The γ globulin fraction also appears to be involved in the colloidal gold reactions.¹⁰ A positive reaction in the thymol turbidity test on the other hand seems to depend chiefly on the β globulin fraction and the lipids.¹¹

Although the values for the partition of the proteins by electrophoresis have been compared with the results of liver function tests based on an alteration of serum protein, there is a paucity of data to compare the values of albumin and globulin determined by precipitation with methyl alcohol. In view of the simplicity of the latter method it seemed desirable to conduct a simultaneous study on a series of normal and pathologic sera to compare the results of the fractionation of the proteins by salt and by methyl alcohol with the cephalin cholesterol flocculation and the thymol turbidity tests.

EXPERIMENTAL

Unhemolysed serum was obtained from postabsorptive venous blood of hospital patients on the medical and surgical wards and from apparently healthy laboratory workers and nurses. The patients were divided into three groups. Group 1 consisted of ten patients with known liver disease. Group 2 represented eighteen cases in which changes in the serum proteins were probably due to nonhepatic causes such as nephrosis with albuminuria and hemorrhage. Group 3 consisted of seventeen patients with miscellaneous medical conditions in which no change in the serum proteins might be expected.

In most of the patients of Groups 1 and 2 at least two specimens of blood were analysed depending on the duration of hospitalization and on the clinical condition. One patient with acute hepatitis was followed throughout a period of two months in which there were abnormal findings. Although many routine laboratory determinations were made the present study is concerned primarily with the two chemical methods of determining the serum albumin and globulin and with the cephalin cholesterol flocculation and the thymol turbidity tests for liver function. Where it is pertinent the results of other determinations are included.

METHOD

The biuret reaction was used to determine the total serum proteins and the albumin in the filtrate after precipitating the globulins with either sodium sulfate or methyl alcohol. The same reagent, corresponding to reagent TP of Kingsley^{2b} was used in each case and was prepared by adding 1,200 ml of 1 per cent crystalline copper sulfate to 6,000 ml of 14 per cent sodium hydroxide. The reagent was standardized frequently for total protein and for albumin with serum and with alcoholic or sodium sulfate filtrates of known protein nitrogen content determined by macro Kjeldahl for total nitrogen and by nesslerization for nonprotein nitrogen.

Total Protein—Total protein was determined in duplicate by adding 0.15 ml of serum to 10 ml of biuret reagent in colorimeter tubes. After fifteen minutes the solutions were read in an Evelyn photoelectric colorimeter at 540 $m\mu$, with a blank tube containing 10 ml of the reagent and 0.15 ml of 0.9 per cent sodium chloride set for 100 per cent transmission. Some samples of serum were slightly turbid, but the solutions obtained on addition to the biuret reagent were clear except in one or two instances. About 2 ml of ether were added to every sample of turbid serum after mixing with the reagent and the solutions were then read in the colorimeter under the layer of ether. In every case the results were the same as those obtained in duplicate samples of the same serum without the use of ether. The protein content was calculated from a standard curve, which remained unchanged on repeated standardizations for several months. This curve was prepared from determinations of pooled serum of known protein nitrogen content which was diluted serially one to ten times with 0.9 per cent sodium chloride. The values of optical density, $2 - \log$ of the transmission, were then plotted against concentration in per cent total protein. All the points fell on a straight line, but there was a slight deviation in the lower part of the curve, corresponding to a dilution of eight to ten times.

Albumin by Salt Precipitation—The method of Kingsley^{2b} was used in somewhat modified form. The globulin was precipitated by adding 0.5 ml of serum to 9.5 ml of 9.4 per cent sodium sulfate contained in 15 ml centrifuge tubes. About 2 ml of ether were added and the tubes were stoppered and shaken vigorously several times. Within five minutes after mixing, the tubes were covered with rubber caps and centrifuged. A pipette was then inserted under the ether layer and the interphase precipitate, and 3 ml of the clear aqueous solutions were transferred to Evelyn tubes containing 10 ml of biuret reagent. A blank tube was prepared with 3 ml of a mixture of 9.5 ml of sodium sulfate solution and 0.5 ml of water added to 10 ml of the biuret reagent. The results were estimated from the reading of the colorimeter at 540 $m\mu$ on a standard curve prepared in the same way as for total protein, except that varying dilutions of a globulin filtrate of known protein content were used instead of whole serum. All the determinations were made in duplicate by precipitating separate samples of the same sera. Usually the results of the duplicate determinations agreed well within 0.1 Gm per 100 ml of serum, and the results were discarded if the agreement was less than 0.2.

Albumin by Precipitation With Methyl Alcohol—The method of precipitation was that of Pillemer and Hutchinson⁴. The serum and reagents were placed in a bath of ice water, where they were mixed, and the precipitated globulin was filtered in the refrigerator. Albumin was determined by adding 1 ml of the cold filtrate to 10 ml of the biuret reagent and reading the resultant color in the Evelyn colorimeter at 540 millimicrons. The results were calculated from a standard curve prepared from the values of ten diluted samples of an alcoholic globulin filtrate of known protein nitrogen, determined by macro Kjeldahl which was corrected for nonprotein nitrogen. The accuracy of the method was checked with a series of thirty determinations precipitated in duplicate which, for the most part, agreed within 0.1 Gm of albumin per 100 ml of serum. All the other determinations were made on duplicate samples of the globulin filtrates.

Thymol Turbidity Test—The method of Shank and Hoagland⁷ was used in an essentially unmodified form. The reagent was prepared and standardized with mixtures of 0.09 per cent barium chloride and 0.200N sulfuric acid, using an Evelyn colorimeter with 660 filter. For the tests, 0.15 ml of serum was added to 10 ml of the reagent, and the readings were compared against a blank tube containing only the reagent, which was set for 100 per cent transmission.

Cephalin Cholesterol Flocculation Test—The test was made with commercial antigen⁸ according to the method of Hanger⁵ by adding 1 ml of the antigen emulsion to a mixture of 0.2 ml of serum and 4 ml of 0.85 per cent sodium chloride in 15 ml centrifuge tubes. After mixing, the tubes were stoppered and placed in a dark closet at room temperature, and the amount of flocculation in the tubes was estimated, without centrifugation, after twenty-four and forty-eight hours. Since it was difficult to estimate differences in the amount of

*Obtained from Difco Laboratories, Detroit, Mich.

precipitate by measurement in graduated tubes the supernatant fluid above the sedimented precipitates was compared with standards which were prepared at the time of the readings. The standards consisted of serial dilutions of a mixture of 2 ml of the antigen emulsion and 84 ml of 0.85 per cent sodium chloride corresponding to the dilution of the antigen with serum. The following criteria were used to evaluate the results 1 plus is intermediate between the undiluted standard and a dilution of twofold, 2 plus is twofold 3 plus is four to eightfold, 4 plus is water clear.

RESULTS AND DISCUSSION

It is seen in Table I that the albumin globulin ratio in eleven normal healthy individuals varied between 1.46 and 1.92 by the method of precipitation with methyl alcohol. These values compare favorably with those obtained in normal subjects by the electrophoretic method.¹ The albumin globulin ratios determined by fractionation with salt are higher in almost every case but this is consistent with recent findings¹ that the α globulin fraction remains in solution in about 21 per cent sodium sulfate. As was to be expected in normal individuals, the thymol turbidity and the cephalin cholesterol flocculation tests yielded normal values.

In Table II it is seen that the values of the albumin globulin ratio determined by fractionation with methyl alcohol follow the clinical course in liver disease very well and the values of the ratio determined by salt fractionation appear only slightly less consistent. In the cases of parenchymatous liver disease which are presented the values of thymol turbidity also seem to afford a reliable guide but the cephalin cholesterol flocculation test in our experience served only to indicate the period in which the disease was at its height.

In Patient H. S. there was a slight clinical improvement early in the disease, although both the albumin globulin ratio and the thymol turbidity test remained essentially constant. About five weeks after admission during a relapse in the clinical condition of this patient the cephalin cholesterol flocculation test became positive. Thereafter with the onset of steady clinical improvement the values of both the protein ratio and the thymol turbidity test gradually returned to normal. At biopsy on June 12 the liver showed evidence of almost complete healing. From the values of the albumin globulin ratio it would seem that the hepatic function had returned to normal.

In Patient M L a biopsy on June 11 showed extensive liver damage. This was in agreement with the low ratio of the proteins and the high values of the thymol turbidity. In the case of Patient B R, who showed a typical clinical picture of acute hepatitis the values of the ratio and the thymol turbidity were also consistent. Patient B C had a typical case of cirrhosis of the liver. He was admitted to the hospital gravely ill, but steadily improved under treatment and was finally discharged. Several weeks later the patient was sufficiently well to return for the last examination. In Table II it is seen that the values of the albumin-globulin ratio were quite consistent with the steady improvement shown clinically, although the thymol turbidity and cephalin-cholesterol flocculation tests remained elevated and essentially constant.

In obstruction of the common duct and in diffuse carcinoma of the liver the values of the albumin-globulin ratio determined with methyl alcohol are consistently depressed. This depression was especially of value in the case of Patient I T (Table II), whose liver was riddled by metastatic carcinoma of renal origin and who died very shortly after laparotomy from hepatic and renal failure. Yet in his case as well as in the other case of extensive carcinoma, and

in the cases of relatively long standing obstructive jaundice the thymol turbidity and cephalin cholesterol flocculation tests gave normal values and afforded no index to the marked hepatic damage present

In Table III are presented the results of all the nonhepatic cases studied in which a derangement of the serum proteins might be expected. The patients of this group had conditions entailing a loss of protein either in the urine or as a result of hemorrhage. Edema was common. It is seen that the albumin globulin ratio determined by methyl alcohol precipitation was approximately

normal in only two of the seventeen patients. The clinical diagnoses in these cases were Boeck's sarcoidosis and chronic lymphadenitis. It is noteworthy that the thymol turbidity test was elevated in both. Another patient, Patient B L who was diagnosed as having multiple myeloma, had a markedly depressed ratio, but both the thymol turbidity and the cephalin-cholesterol flocculation tests were normal. The increased β globulin fraction which other workers find in this disease¹³ did not yield elevated values in the thymol turbidity test.

In Table IV are seen the results in an unselected group of miscellaneous hospital patients in whom there was no suspicion of liver disease or of any other pathology that might cause a derangement in the serum proteins. Only three of the seventeen patients showed a marked depression of the albumin globulin ratio. Of the seventeen patients, four showed an elevated thymol turbidity and three a positive cephalin-cholesterol flocculation.

It seems clear that the albumin-globulin ratios determined by precipitation with methyl alcohol more accurately reflect the severity of the pathology in patients with liver disease than any other individual test and may be used as an index of the extent to which the liver is involved. In Tables III and IV it is seen that the abnormalities in the serum proteins due to nonhepatic causes can be correlated quite well with the clinical picture, but the values obtained by salt fractionation appear to be less consistent than those obtained by precipitation with methyl alcohol. In our experience the results of the latter method are even more reliable than the values of the thymol turbidity test provided

we rule out clinically, as far as possible, nonhepatic causes for a derangement in the serum proteins. Particular emphasis is placed on the fact that Table IV contains the results in all the cases studied where a derangement was not expected clinically.

Whereas Shank and Hoagland found the values of the thymol turbidity test in forty six normal subjects to range between 0 and 4.7 units, our range for a smaller series of normal healthy individuals is 0 to 1.5 units. One value of 9.5 units was discarded, since it was found in a man who was known to use alcohol to excess and in whom the albumin globulin ratio by methyl alcohol precipitation was 0.92. The cephalin cholesterol flocculation test in this individual was 2 plus. The latter test in our series of eleven normal subjects showed seven with a value of 2 plus and four with a value of 1 plus. A reading of 3 plus or 4 plus is generally considered abnormal for the Hanger test. Since control tubes without added serum were always 1 plus or less, this high proportion of apparently healthy individuals with values of 2 plus is disturbing. We have no explanation for the discrepancy between our results and those of other workers who almost invariably obtained negative values with commercial antigen in normal subjects.⁸ However, in spite of this discrepancy our results with the cephalin cholesterol flocculation test seem quite consistent and apparently indicate the height of the disease in parenchymatous liver involvement. We stress the fact that our procedure entails an objective comparison of the unknown sera with standard tubes prepared from the antigen and saline solutions.

Of interest in connection with the serum proteins in liver dysfunction is the high value of the thymol turbidity test found in Patient B. S. (Table III) a few days before death. The total proteins in this patient had remained constant at about 4 Gm. per 100 ml. for a month, and there was a constant elimination in the urine of about 15 Gm. of protein per day. Transfusion was not resorted to, but the patient was kept on a high protein diet which was apparently sufficient to replace the albumin that was excreted. Death finally came as a result of an abdominal infection which may have involved the liver. Permission for an autopsy was not obtained. Although the absolute amounts of albumin and globulin were essentially constant in three different determinations over a period of three weeks, the thymol turbidity test was positive only in the last determination with a value of 7.9 units.

In conclusion the present study demonstrates the importance of the albumin globulin ratio in the study of liver disease. Neither the thymol turbidity nor the cephalin cholesterol flocculation tests indicated an involvement of the liver in the cases of obstruction of the common duct and of carcinoma of the liver which were studied, but all showed a marked depression of the ratio. There is good reason to believe that the values of the proteins obtained by precipitation with methyl alcohol are a true estimate of the partition that is shown by electrophoresis. Although it is obviously not possible in every case to be certain that nonhepatic causes for a derangement of the serum proteins are not present, our results appear encouraging. We feel that once hepatic involvement is recognized, the albumin globulin ratio becomes a valuable means of

evaluating the degree of the involvement. It is also of aid in gauging the clinical progression or regression of the cases under study, and this can be of prognostic significance.

SUMMARY

The results of a simultaneous study of the albumin globulin ratio, the thymol turbidity test, and the cephalin-cholesterol flocculation test in eleven normal subjects and in three groups of hospital patients are presented. The albumin-globulin ratio, as determined by fractionation with methyl alcohol, was found to be consistently depressed and to agree with the general clinical picture in ten cases of liver disease. The thymol turbidity test also was found to give consistent results in four cases of parenchymatous liver disease, but offered no index to the dysfunction in two cases of liver carcinoma and in four cases of relatively long-standing obstructive jaundice. The cephalin-cholesterol flocculation test seemed only to indicate the height of the disease in the four cases of parenchymatous liver disease which were studied.

That nonhepatic causes for a decrease in the albumin globulin ratio can be excluded with a fair degree of certainty is shown by the low incidence of a depressed ratio found in a group of miscellaneous hospital cases which did not include patients in whom a low ratio might be expected from causes entailing a loss of serum protein. It is concluded that the albumin globulin ratio may be utilized with profit in the study of liver disease, since it seems to offer information which is as good as either the thymol turbidity or the cephalin-cholesterol flocculation tests.

The authors are grateful to Dr. Joseph Felsen, Director of Research and Laboratory, for advice and encouragement.

A DILUTION TURBIDITY TEST IN THE SERUM IN COMPARISON WITH THE THYMOL TURBIDITY AND CEPHALIN CHOLESTEROL FLOCCULATION TESTS

FRITZ DREYFUSS, M D
NEW YORK, N Y

SINCE the detection of hyperglobulinemia is of importance, a large variety of methods has been employed to discover an increase, either absolute or relative, in plasma globulins. Whereas previous work has tried to link the results of the tests for hyperglobulinemia with the amount and distribution of protein determined by chemical methods (salting-out techniques¹), more recent studies have attempted to correlate some of these well established clinical tests with definite serum protein electrophoresis. It soon became evident that rather complicated mechanisms are involved and not simply an increase of a single, well-defined fraction of the serum protein. An inquiry into the nature of Hanger's cephalin-cholesterol flocculation test² (C C F), for example in infectious hepatitis, has led to the conclusion that the gamma globulin content of the serum has to be increased and that its albumin content as well as the protective action of this albumin has to be decreased in order to give a positive result in this test.³ The substance responsible for the turbidity in MacLagan's thymol turbidity test^{4, 5} (T T T) was originally assumed by MacLagan himself to be composed of gamma globulin, phospholipids, cholesterol, and thymol, whereas Cohen and Thompson⁶ reported that the thymol reagent reacts chiefly with the beta globulin fraction of the serum. In addition, Recant, Chargaff, and Hanger⁷ have demonstrated that the mechanisms of the two tests are different. They found that the gamma globulin fraction is not necessary for a positive thymol test but is essential for a positive cephalin cholesterol flocculation and that the presence of lipids is essential in the thymol turbidity test but has no influence in the cephalin-cholesterol flocculation test. According to these workers, the albumin fraction, on the other hand, is of importance for the cephalin-cholesterol flocculation but not for the thymol turbidity test. Cohen and Thompson, it is true, have also stated that there is not only no correlation between a gamma globulin increase and the thymol turbidity test units, but also that the same holds true for the beta globulin in their experiments. They therefore consider a change in the nature or amount of lipids bound to the beta globulin fraction as a possible agent. Kunkel and Hoagland⁸ in a very elaborate communication have recently presented evidence that the turbidity measured in the thymol turbidity test depends on protein as well as on lipids precipitated. The varying lipid content of sera, however, determines different degrees of turbidity only in the presence of serum globulin likely to produce the reaction. Their electrophoretic analysis of the thymol precipitate after lipid removal demonstrated the protein to be a gamma globulin, study of the sera after separation from the

From the Medical Division Montefiore Hospital Chief Dr Louis Leiter
Received for publication Feb 9 1948

thymol precipitate, in contrast showed a definite decrease in beta globulin. The addition of large amounts of albumin *in vitro* proved to have a slight inhibitory effect on the thymol precipitation. The authors conclude that the thymol turbidity in infectious hepatitis depends on the presence of lipids and of abnormal lipid protein complexes migrating in the beta globulin fraction of the serum. The gamma globulin fraction of serum also plays an important role in the reaction."

Kala azar has long been the yardstick by which the efficacy of methods for detecting hyperglobulinemia was measured. Out of the necessity for a simple screening test for this disease a blood or serum dilution test was devised by Brahmachari⁹ who used a 1:2 to 3 dilution with distilled water. Ray¹¹ in 1921 and Sia¹² in 1924 suggested a 1:200 or 1:30 dilution respectively using whole blood. It is of interest to mention that Naumman¹³ showed that water saturated with alveolar air (40 mm Hg CO₂) precipitates certain globulins from the serum.

Our interest in this subject was aroused by the recent determination of this dilution fraction and of cold precipitable globulins by Wertheimer and Stein in kala azar^{14, 15} and by Wertheimer¹⁶ in other hyperglobulinemic states. In the course of an investigation into this cold fraction it seemed worth while to re-evaluate the procedure of serum water dilution. Because of the uncertainty concerning the nature of the material precipitated and because of the findings that became evident during this work, we prefer to call the test as performed here a dilution turbidity test (D.T.T.). Since it was intended to find out whether this reaction is indicative of some distinct hyperglobulinemic pattern the thymol turbidity and the cephalin cholesterol flocculation tests were carried out at the same time. They may serve as possible range finders for the elucidation of this hypothetic pattern (roughly beta or gamma globulin lipid dependence, and so forth).

MATERIAL AND METHODS

Sera of patients from various departments of this hospital were examined.

The dilution test was performed in the following way: 0.4 cc of fresh serum were diluted into 60 cc of doubly distilled water (1:15 dilution) and gently mixed. The resulting turbidity was observed after a few minutes and its intensity was measured in a Fisher photometer (filter 660 as used for the thymol turbidity determination) after thirty minutes. The readings so obtained were then converted into units using the barium sulfate standards of Shank and Hoagland¹ just as for the determination of units in the thymol turbidity test. It soon became evident, first that any value exceeding 25 units represented an increase in this fraction and consequently an abnormal result and second that a twenty-four hour flocculation could frequently be observed. This flocculation appeared in many of the sera which showed an abnormal increase in turbidity.

The eye quickly becomes used to gauging low normal and high values even without the use of a photometer.

The serum so diluted loses its color entirely except in the presence of a fair increase in bilirubin, in contrast to the thymol turbidity and cephalin-cholesterol flocculation tests.

The thymol turbidity test was carried out according to MacLagan's original technique with Shank and Hoagland's modification and using the suggestion of MacLagan⁴ and of Neefe and Reinhold¹⁸ that the flocculation which takes place after twenty-four hours in certain sera be noted. Values over 4 thymol turbidity units as well as flocculations of 1 plus to 4 plus were considered abnormal.

The cephalin cholesterol flocculation test was performed according to Hanger's original method.² The test tubes for all three tests were kept in a darkened room as suggested by Neefe and Reinhold¹⁸ for the cephalin cholesterol flocculation test. A plus minus reading was considered negative.

Since this hospital cares mostly for the chronically sick, the material examined reflects this fact in the relatively low number of certain acute conditions commonly examined in a study of this sort. This circumstance, on the other hand, provided us with a chance to become well acquainted with the so-called false positives encountered in performing these tests.

EXPERIMENTAL RESULTS

Early in the course of this investigation it became evident that the dilution turbidity paralleled the thymol turbidity rather closely. However, a certain number of discrepancies occurred. These discrepancies could be divided into two principal groups: first, those apparently due to a real difference in the two fractions of the serum responsible for the two respective reactions, and second, others which proved to be dependent on a time factor in the carrying out of the dilution, both will be discussed later.

It seemed, therefore, of interest to perform several experiments designed to elucidate the relationship between the dilution turbidity and the thymol turbidity on the cephalin cholesterol flocculation and their respective biochemical backgrounds. By and large, procedures carried out by Recant and co-workers⁷ were applied with certain modifications.

The thymol turbidity test and the dilution turbidity test are both performed using distilled water as a diluent, whereas the cephalin cholesterol flocculation is done in normal saline solution. Both the former tests are read after thirty minutes. A series of successive dilutions of normal saline solution demonstrated (Table I) that the dilution turbidity increases with decreasing salt concentration, pointing to its euglobulin nature.

According to McFarlane's technique¹⁹ (repeated lipid extraction with ether and separation of extract by freezing), extracts of several sera were prepared. The thymol turbidity, dilution turbidity, and cephalin cholesterol flocculation of these sera were determined immediately before and after the extraction. As Table II shows, this procedure was followed by a considerable decrease in thymol turbidity and dilution turbidity and, in contrast to the findings of Recant and co-workers,⁷ also by a slight but noticeable decrease in cephalin cholesterol flocculation of about 1 plus. This decrease in cephalin cholesterol flocculation may be due to an alteration of the protein structure caused by the repeated freezings, rather than to the extraction of lipid material.

The dried substance extracted by the freezing process in seven sera did not dissolve in KOH, and it gave a negative biuret reaction in five and a very mildly positive reaction in two of the extracts. The positive reactions may

have been due to a slight contamination of the extract with serum. The extracted substance is apparently a lipid fraction of the serum. It was interesting to note that the extracts of sera having high thymol turbidity and dilution turbidity values prior to extraction yielded a visibly greater amount of substance.

themselves gave positive thymol turbidity and dilution turbidity tests but negative cephalin cholesterol flocculation tests (Table IV).

Similarly the following two analyses bear out the conformity of behavior of dilution turbidity and thymol turbidity in contrast to cephalin cholesterol flocculation.

The dilution turbidities in the blood sera of three healthy rabbits were 10, 10, 10, and the thymol turbidities were 10, 10, and 0.5, respectively, the cephalin-cholesterol flocculations were 4 plus, the two latter being in agreement with the findings of Recant, Chaigaff and Hanger.⁷

Human immune serum globulin* was tested. Table V demonstrates the results, proving that this product contains a large amount of cephalin cholesterol flocculation producing substance (gamma globulin) and apparently very little of the materials responsible for the two other tests.

†Flocculation starting after about thirty minutes

We feel justified in concluding from the foregoing experimental and biologic findings that the serum fraction responsible for a positive dilution turbidity test is closely related to the one responsible for a positive thymol turbidity test.

At the beginning of our work, a fair proportion of discrepancies between dilution turbidity and thymol turbidity (the dilution turbidity was too low compared with the thymol turbidity) was found to be due to a delay in performing the tests. The later a dilution turbidity test was carried out, the lower its value was likely to be, there was, however, some turbidity even after five to six hours. Moreover the increased dilution turbidity of pathologic sera showed a definite tendency to persist longer.

Since there was reason to suspect that loss of CO₂ might account for this inconstancy of findings, a series of experiments was performed in order to study this possibility. In these experiments samples of blood were collected under oil, the serum was separated under oil in some of them, and the tests were performed on the sera thus obtained. These results were compared with those obtained on blood collected in the usual way. Table VI summarizes a few of these experiments. The results led to the following conclusions: dilution turbidity tests done on separated sera remain more constant than those done on unseparated sera, dilution turbidity obtained from sera or even from unseparated sera under oil tends to keep constant for a longer time (about as long as the protective action of oil on the CO₂ content can be expected to last, several hours according to Peters and Van Slyke²⁰). However, apparently there are other factors which must have accounted for the rather erratic behavior of the dilution turbidity after six hours or more. With the intention of excluding at

least one other possibility an attempt was made to poison the active enzyme systems which may be responsible for the deterioration of the dilution turbidity. The addition of 0.05 cc of a 1:10,000 solution of NaCN to 1.0 cc of serum however did not prevent the decrease as observed in the controls.

When the dilution turbidity test is performed in distilled water saturated with CO₂ (according to Naumann¹³) but otherwise following the technique employed throughout our work the values thus obtained are higher than when the test is performed on freshly drawn blood using distilled water alone. The normal upper limit here is probably close to 4 units.

We consequently consider it as probable that the escape of CO₂ is the reason for the gradual lowering of the dilution turbidity values on standing. To avoid using means for controlling this escape and thereby complicating an otherwise simple procedure we recommend that the test be performed shortly after the blood is drawn preferably within one to two hours. Otherwise the serum should be separated from a blood specimen taken under oil and stored under oil in a refrigerator. Even taking these precautions it is best not to delay the test for more than six hours.

In the following tables (Tables VII to X) and statistics only those values are used which were obtained from freshly examined specimens.

CLINICAL RESULTS

In 328 blood specimens taken from 203 patients the following results were obtained. 196 specimens from 105 patients showed a positive result in one or more of the tests performed. The dilution turbidity test was positive in 139, the thymol turbidity test in 160 and the cephalin cholesterol flocculation in 131. All three tests were positive simultaneously in 90 specimens. Only the dilution turbidity and thymol turbidity tests were positive in 34. The dilution turbidity test and cephalin cholesterol flocculation test were positive in 6. The thymol turbidity and cephalin cholesterol flocculation tests were positive together in 14. The dilution turbidity test was positive alone in 9, the thymol turbidity test alone in 22 and the cephalin cholesterol flocculation alone in 21.

Table VII, which summarizes the cases of liver and biliary tract disease, shows the rather close parallelism of the tests with a few notable exceptions. Patient W R, following gastroenterostomy and vagotomy for duodenal ulcer and obstruction, presented a late postoperative picture of questionable obstructive jaundice possibly combined with mild parenchymal damage. Since no clear-cut diagnostic conclusion could be reached, the evaluation of the slight discrepancy in the tests is obviously impossible. Patients N P, C S, M F, and F W, patients with neoplastic disease, showed discrepancies between the dilution turbidity and the thymol turbidity tests; patient N P showed cirrhosis and carcinoma of the liver on surgical exploration.

It may be stated here that most of the discrepancies between dilution turbidity and thymol turbidity eventually fitted into three groups: neoplastic diseases, congestive heart failure, and, to a smaller extent, diabetes. In diabetes the thymol turbidity test is occasionally positive.

In Table VIII the cases of neoplastic disease are reviewed. Those belonging in this group but already reported in Table VII are not repeated but are included in the statistics. In eleven specimens out of sixty-five (excluding the rather uniform group of multiple myeloma) a discrepancy between dilution turbidity and thymol turbidity was noted, and in five, a discrepancy between the thymol turbidity test and the cephalin-cholesterol flocculation test.

None of the e presented a Bence Jones proteinuria
†Bence Jones proteinuria present

The small group of four cases of multiple myeloma presents an interesting feature insofar as, with one exception—a normal value—all the dilution turbidity and thymol turbidity values were low and all the cephalin cholesterol flocculations were negative. This is so, irrespective of the total protein and especially globulin levels which in three cases were high and in one low.

Table IX summarizes only those cases of congestive heart failure in which one or more of the tests were positive. In ten specimens out of fifty-seven taken from patients with congestive failure dilution turbidity and thymol turbidity did not conform; eight of them presenting an increased thymol turbidity and normal dilution turbidity and in fifteen there was an incongruity between the thymol turbidity test and the cephalin cholesterol flocculation.

Eleven specimens taken from nine patients with active tuberculosis, mostly advanced pulmonary tuberculosis (three of them were included in Table VII which reviews liver disease) showed ten positive dilution turbidity tests and ten positive thymol turbidity tests, all in the same specimens and six positive cephalin cholesterol flocculation tests.

Some cases of special interest are presented in Table X. In accordance with the findings of Weithamer and Stein²⁴ two cases of subacute endocarditis showed increased dilution turbidity and also conformed with their findings: a cold fraction was present in these sera. Carter and MacLagan² also have reported on the positivity of the thymol turbidity test in this disease. Liver damage though is hardly to be ruled out in subacute bacterial endocarditis. Positive liver tests have been reported in infectious mononucleosis by several authors.^{2, 23} It seems worth while emphasizing the increased values in the three patients with atypical pneumonia examined, a finding which we have not encountered in the few patients with other types of pneumonia examined. We intend to follow up this finding in an adequate series of atypical pneumonias.

*Rheumatic heart disease

†Arteriosclerotic heart disease

‡Hypertensive cardiovascular disease

§Arteriosclerotic hypertensive cardiovascular disease

A group of eleven cases of rheumatoid arthritis presented a high proportion of positive dilution turbidity and thymol turbidity tests. From this point of view the disease is the subject of a study at the present time.

*Rheumatic heart disease.

Positive flocculation reactions (twenty four hour reading) are marked plus to 4 plus according to their degree where observed but in the first few weeks of this work insufficient attention was paid to this phenomenon. No statistical conclusions, therefore, are drawn from them. We could not in contrast to Neeffe²⁴ observe an advantage of the thymol flocculation test over the thymol turbidity test as a more sensitive indicator for liver damage we found it positive only whenever the thymol turbidity was over 4. We made the same observation for the dilution flocculation and looked at the flocculation reactions only for their confirmatory value.

DISCUSSION

The behavior of the dilution turbidity toward NaCl and distilled water and toward lipid extraction and addition respectively and its negative result in tests performed on rabbits' blood and on immune globulin demonstrate its close relationship to the thymol turbidity test. This relationship furthermore is borne out by the clinical data. We even venture to suggest that a considerable part of the precipitation in the thymol turbidity test is due to the diluting effect of the distilled water. Certain differences however (as both the rapid deterioration of the former fraction and a sizable number of discrepancies in the clinical material indicate) make it appear improbable that the respective fractions responsible for the two tests are identical they may overlap though and be very close to each other.

In accordance with Recant, Charzaff and Hanger,⁷ Watson and Rappaport,²⁵ Neeffe²⁴ Mateer and co workers,^{28, 2} Havens and Marek²⁹ and Cohen

and Thompson,⁶ we conclude from our experience that the cephalin cholesterol flocculation indicates a different serum pattern from the one responsible for the thymol turbidity test and, for that matter, for the dilution turbidity test.

Reviewing the clinical results, a few findings require further comment. Among the nine cases in which the dilution turbidity alone was positive, there were three in which the thymol turbidity value was 4, a value considered positive by Mateer and co-workers,²⁶ one was a case of congestive heart failure, and one a probable intra-abdominal malignant tumor. Among the twenty-one cases in which the thymol turbidity test alone was positive, four represented malignant diseases, five congestive failure, and five diabetes. Of six specimens in which the dilution turbidity test and the cephalin-cholesterol flocculation test were positive together, four had a thymol turbidity of 4 and one of 3.5, and one was from a patient with a malignant disease. The group where the thymol turbidity test and the cephalin-cholesterol flocculation test were both positive together (four specimens) is made up of cases of congestive failure and neoplastic disease with the single exception of one case of diabetes.

Irrespective of these considerations, when summarizing our figures as given, it becomes evident that the association of findings of the dilution turbidity and thymol turbidity tests is not merely a matter of chance, these two tests are positive together in 124 specimens, the dilution turbidity test and cephalin cholesterol flocculation together in 96. Since the standard error of difference is 4.95, the difference between both series of findings exceeds by five and one half fold the standard error of difference.

The majority of the findings belongs to the group in which all the tests were positive. Most diseases, especially those of the liver, which cause profound protein disturbances apparently are able to produce positive tests in several groups. In a severe parenchymatous disease of the liver such as infectious hepatitis, the results of most of the valuable liver tests may well be expected to be positive, together at the same time or at least following each other in different phases of the disease, whether the tests belong to the hepatocellular or the cholangiolar type (Watson and Hoffbauer²⁹).

As Cantalow³⁰ and others have shown, other diseases of the liver are less likely to produce a large number of different positive tests simultaneously. Hanger has pointed out repeatedly that some cases of malignant diseases of the liver, primary or metastatic, usually fail to produce a positive cephalin cholesterol flocculation. Watson and Rappaport²⁵ mention in their table of disagreements between cephalin-cholesterol flocculation and the thymol turbidity test four cases where, on the contrary, the cephalin-cholesterol flocculation was 1 plus to 2 plus and the thymol turbidity test was negative.

Congestive failure of the heart may attack the liver in various ways and so produce varying functional effects expressing themselves in incongruous results of tests.²¹⁻³¹ It is conceivable that in both groups of cases, neoplastic diseases on the one hand and the congestive damage of the liver on the other, different cell units may be affected in different degrees and ways, and, as for the first category, the damage might not necessarily be in the liver.

The determination of the dilution turbidity and flocculation may prove itself useful for several reasons. It supplies, in our experience, most of the information provided by the thymol turbidity and flocculation test. Its departure from the thymol test may, in addition, turn the attention to one of the disease groups mentioned in which this occurs, and it may be helpful in the classification of a case of striking hyperglobulinemia. The dilution turbidity test is easily carried out and, after some experience in its use has been acquired, may even be employed as a bedside procedure.

SUMMARY

The procedure of diluting serum with distilled water was carried out and the resulting turbidity was read photometrically. This dilution turbidity test was compared with Muelagau's thymol turbidity test and Hanger's cephalin cholesterol flocculation test.

It was noted that at a dilution of 1:15 the dilution turbidity closely parallels the thymol turbidity.

Experimental evidence confirms this observation of a close relation between these two tests, the technique of the procedure, the behavior of the dilution turbidity toward water and sodium chloride, its values before and after lipid extraction of the sera, its behavior with rabbits' blood and human immune serum globulin, and the fact that it flocculates within twenty-four hours when present in increased amounts, all put the dilution turbidity test beside the thymol turbidity test rather than the cephalin cholesterol flocculation test.

Conforming with evidence obtained by others, a certain difference in mechanism between the thymol turbidity test and the cephalin cholesterol flocculation test also is confirmed by our experiments and clinical experience.

There is, however, an obvious difference in the results of the thymol and dilution tests in a small number of cases as well as in the experimental results. The discrepancies between the two tests as observed in clinical cases usually fall into the categories of neoplastic disease, congestive heart failure, and diabetes. The serum components responsible for the two respective tests therefore cannot be identical but may overlap.

The dilution turbidity test may serve as a simple test apparently giving most of the information supplied by the thymol turbidity test. It may further more confirm and occasionally modify the result obtained in a thymol test.

I wish to thank Dr. E. Wertheimer for arousing my interest in this field, Mr. G. Ross for his kind help and interest, Dr. L. Leiter, Dr. F. M. Hanger, and Dr. L. Recant for valuable suggestions, and the house and laboratory staffs of Montefiore Hospital for their fine cooperation.

EXPERIMENTAL STUDIES ON THE INTRAVENOUS INJECTION OF A FAT EMULSION INTO DOGS

H C MENG, M D PH D * AND SMITH FREEMAN M D , PH D
CHICAGO, ILL

IT IS important to be able to provide complete parenteral nutrition for human beings. To accomplish this it seems necessary to have a stable, nontoxic fat emulsion suitable for administration by vein. The literature contains numerous reports¹⁻⁷ recording the efforts of other investigators in this direction. From studying these reports it is apparent that none of the emulsions thus far prepared is entirely free from toxic effects.^{5,7} Emboli, anemia or liver damage appear to be the most common complications arising from the injection of intravenous fat.

The following is an account of our most successful experiences in attempting to prepare a stable nontoxic fat emulsion suitable for intravenous use.

EXPERIMENTAL PROCEDURE AND RESULTS

The problem may be divided into three parts: (1) preparation of a uniform stable, finely divided fat emulsion, (2) a study of the physiologic effects of the emulsifying agents and of the complete fat emulsion and (3) evidence concerning the utilization of fat contained in the emulsion.

Preparation of a Uniform Stable Fat Emulsion.—

The emulsifying agents studied included Tweens, Spans,[†] soya bean phosphatides,[‡] mono and diesters of glycerol phosphate esters of long chained hydrocarbon alcohols, gums, plasma and bile salts.

Many substances were tried alone or in combination with one another. The oils used were coconut, corn or butter oil. The fat soluble agents were dissolved in the fat and the water soluble substances in water prior to mixing the water and oil together. Dextrose, Karo syrup, or dextrans were also dissolved in the aqueous phase in some instances. Preliminary studies on emulsification usually were made with a hand homogenizer. If these experiments appeared promising as judged by the particle size and ease of emulsification a larger batch of material was emulsified by means of a Cherry Burrell Viscolizer.[§]

The following procedure and substances were finally adopted as yielding a satisfactory emulsion containing a minimum of emulsifying agents. Fresh sweet butter was melted and the oil separated by centrifugation after which it was washed three times using four volumes of hot distilled water for each washing. Five grams of Span 20 and 4 Gm. of pure soya phosphatides (Asolectin) were added to every 100 Gm. of butter oil.

*From the Departments of Physiology and Experimental Medicine Northwestern University Medical School.

Received for publication Feb. 9, 1948.

†Present address: Department of Physiology, Vanderbilt University Medical School, Nashville, Tenn.

‡Tweens and Spans are surface active agents produced by the Atlas Powder Company, Wilmington, Del.

§Purified Soya Phosphatides, Asolectin, a product of Associated Concentrates, Inc., Atlanta, Ga.

§The authors wish to acknowledge their indebtedness to the Cutter Laboratories, Berkeley, Calif. for the funds used to purchase the Viscolizer.

The mixture was heated and mixed on a steam bath until dispersion was complete. One hundred grams of dextrose and 1 Gm of sodium cholate* were dissolved in sufficient water to make 883 ml of solution. The butter oil and dextrose cholate solution were then stirred together and poured into the homogenizer. Usually 10 to 15 liters of emulsion were prepared at one time. This amount required four to five pounds of butter.

The mixture was passed through the Viscolizer five times at a pressure of 3,000 to 4,000 pounds per square inch †. At the end of this procedure the milky white emulsion was filtered through gauze into 500 ml Erlenmeyer flasks (400 ml to a 500 ml flask) and the flasks were stoppered with cotton. The flasks of emulsion were autoclaved twice within twenty-four hours at 10 pounds pressure (113 to 114° C) for ten minutes. Part of each batch was incubated for forty-eight hours at 37.5° C, and 1 ml was added to fluid thioglycollate broth and cooked meat broth media. The inoculated media were incubated for forty-eight hours, then streaked on blood agar plates and incubated aerobically and anaerobically. The bacteriologic tests were negative when the emulsion was sterilized as described ‡. The pH of the emulsion after autoclaving was 6.3 to 6.5. The flasks of emulsion were then stored at room temperature till used. The particle size of the emulsion, measured by means of an objective micrometer, ranged from 0.5 to 2 μ in diameter and was quite uniform. Emulsion allowed to stand for two months or more in the laboratory showed little change in gross or microscopic appearance. Freezing and thawing caused a large portion of the fat to separate from the emulsion. Some increase in particle size and a tendency to cream result from long standing.

*Wesson's salt mixture⁹ was used in all the synthetic diets.

The effects of the emulsifying agents were studied by preparing emulsions identical in every respect with those just described except that they contained no butter oil. The acute experiments were carried out on dogs under Nembutal anesthesia. The longer term feeding experiments were done on animals that had been dewormed and had undergone preliminary observations in the laboratory for several weeks prior to use. These animals were confined in cages which permitted a quantitative collection of urine. Fifty ml of 15 per cent (by volume) hydrochloric acid and 1 ml of 10 per cent thymol solution in 95 per cent alcohol were used as preservatives, and urine was collected for a three-day period weekly during experimentation.

The partly synthetic diet (Table I) supplying ninety-three calories per kilogram per day was fed to all animals on metabolic experiments during the control period. A low carbohydrate diet (Table II) was fed to the dogs injected with emulsifying agents (in 10 per cent dextrose), while the fat injected animals received a fat free low carbohydrate diet (Table III). However, the animals received isocaloric diets throughout the experimentation.

*Prepared from cholic acid obtained from G. H. Breon & Co. Inc. Kansas City, Mo.

†During homogenization the temperature of the solution rises from 27° C to approximately 45 to 50° C.

‡The tests for sterility were performed by Dr. Evelyn P. Tilden of the Bacteriology Department of the Dental School, Northwestern University.

3.146 Gm per kilogram as dextrose were given by vein furnishing 1.9 calories

In the longer term experiments the animals were injected while secured on their sides on a canvas frame. The emulsion or emulsifying agents were injected six days per week through a 21 gauge needle into the veins of alternate legs. A rate of approximately 15 ml per minute for a dog weighing 12 kilograms was used in all experiments. Sterile precautions were observed insofar as this was possible. Injection was by means of a plastic tubing secured in the external jugular vein in some instances.

Immediate Effects of Injection of the Emulsifying Agents or Fat Emulsion on Dogs—The effects of infusing the emulsifying agents or fat emulsion on the arterial blood pressure and on the flow of thoracic duct lymph, hepatic bile, and urine were determined*. After a one half to one hour control period infusion was begun and continued at the rate of 0.12 ml per kilogram per minute for the next four hours, after which observations were continued for another hour or longer. Table IV summarizes the results on dogs that received the emulsifying agents (three dogs) or the fat emulsion (five dogs). Blood pressures were not included for in no instance were they altered in either group of dogs. Bile flow

The procedure for these measurements was briefly as follows. An animal was anesthetized with Nembutal (1 grain for every 5 pounds) and secured on his back. A mercury manometer was connected with the left carotid artery by thick walled rubber tubing and a glass cannula filled with citrate solution. Through a right rectus incision the common bile duct was exposed and cannulated and the cystic duct ligated. A small bore rubber tube was connected to the cannula and brought to the outside by means of a stab wound in the right side. The thoracic duct was exposed in the left supraclavicular fossa and cannulated after which the lymph was collected in test tubes containing a small quantity of potassium oxalate. The ureters were cannulated at the brim of the pelvis and urine was collected from small bore rubber tubes attached to the glass cannulas and exteriorized through perineal stab wounds.

tion The nitrogen balance was positive throughout the injection period as it was during the period of control observations for both groups of dogs. These results are shown in Figs 1 and 2

Fig 1—Showing a nitrogen retention (columns) and gain in body weight during daily injections of emulsifying agents similar to those during the control periods

Fig 2—Showing a nitrogen retention (columns) and gain in body weight during periods of daily injections of the fat emulsion similar to those during the control periods

The total fat injection for each dog was as follows: Dog 1 714 Gm, Dog 7 1398 Gm, Dog 8 979 Gm, Dog 9 871 Gm, Dog 10 714 Gm, Dog 11 979 Gm, Dog 12 871 Gm.

Blood chemistry and liver function There was no change in total plasma protein or in plasma nonprotein nitrogen in animals infused either with emulsifying agents or fat emulsion (Tables IX and X). There was no evidence of liver damage as judged by the rose bengal clearance test and by serum phosphatase determination in either group of dogs (Tables IX and X). One dog (Dog 9) showed a slight elevation of serum phosphatase. The urinary albumin and sugar tests were all negative throughout.

Post-mortem examination at the end of the four-week injection period for dogs infused both with emulsifying agents and fat emulsion demonstrated no gross abnormalities. Microscopically, Dogs 9B and 9C showed normal structure of liver and kidney, and no increase in fat deposition in these organs was demonstrated. In the fat injected animals, both Dogs 7 and 8 showed normal lungs, and no abnormalities were observed in the liver and kidney sections of Dog 8. However, in Dog 7 stainable fat granules were present in the liver and Kupffer cells, especially in the periportal areas. In the kidney section of this dog there was a diffuse, faintly positive fat stain in the cytoplasm of the distal convoluted tubules. No globules of fat were demonstrated in the glomeruli. The hematoxylin and eosin stained sections of this kidney revealed an occasional mass of pink material compressing the glomeruli and occupying a portion of the space within Bowman's capsule. No similar material was found elsewhere in the kidney.

— Not determined

Fig. 3—Showing the average increase and rate of removal of fatty acids from the serum of two dogs (Dogs M and M₂) injected repeatedly with a 10 per cent fat emulsion (average of all the fatty acid data in Table XI)

The rate of disappearance of intravenously injected fat The fasting serum lipids and the rate of fat disappearance following single and repeated injections were also determined. Total serum fatty acids, cholesterol, and phospholipids were estimated using the methods described for the lymph lipids.

Two dogs (Dogs M1 and M2) were given daily intravenous injections of fat emulsion for two weeks. The amount of fat emulsion given was based on body weight, as was that for the dogs under nitrogen balance study, and the general stock diet was fed ad libitum. Serum lipids were determined during the first day and at the end of the first and second weeks of injections. The total fatty acids concentration of the serum was markedly increased during fat injection. The increase declined as soon as the injection was discontinued or shortly thereafter and returned to normal within seventeen hours. The elevation

of serum phospholipids which occurred toward the end of injection was slight but consistent. The serum total cholesterol demonstrated an initial fall at the end of the first hour during injection, after which it was increased toward the normal level or slightly above. The second fall occurred one hour or so after injection was discontinued. The results are shown in Table XI and Fig. 3.

Another two animals (Dogs R and H) were given a single intravenous injection of fat emulsion. The serum lipid changes were essentially the same as those of Dogs M1 and M2. When the same animals (Dogs R and H) were given a single injection of emulsifying agents alone (no fat) only a slight change in serum lipids occurred (Table XII).

DISCUSSION

The emulsifying agent is a prime factor in determining the tolerance of an animal for an emulsion¹⁰. Furthermore the stability of an emulsion depends on the emulsifying agent used. All emulsifying agents or stabilizers (surface active agents) are likely to be toxic to a certain extent. Consequently it is important to reduce the emulsifying agents to the minimal amount that will produce a stable fat emulsion. In the present study the amount of the combined emulsifying agents has been reduced to a minimum. Dextrose was added for its osmotic effect and as an aid in making the emulsion more stable.

Egg lecithin has been used as an emulsifying agent in preparing fat emulsions by most investigators.^{1, 6a} Dinham and Bunnshwager¹ also used "demul 14" a mixture of polyglycerolesters to fulfill this purpose. McKibbin and associates^{6a, 6c} found purified soya phosphatides (Asolectin) to be the most satisfactory emulsifying agent. The toxic effects of fat emulsions used in previous studies have been discussed recently.^{6b, 6d} According to the report of Ashby¹ the purity of lecithin may be a factor in causing those reactions.

In the early part of the present study Tween 20 and Span 20 were used as emulsifying agents. The injection of these emulsifying agents produced toxic

manifestations which were mainly due to Tween 20. The toxic manifestations included dilatation of blood vessels, fall in blood pressure, urticaria, urination, defecation, and vomiting. The mechanism of the production of this group of reactions is not well understood. It is probable that these reactions are at least partly due to histamine formation in the body, for they can be prevented by subcutaneous injection of epinephrine five to ten minutes prior to the injection of Tween 20. Benadryl was also partially effective in preventing these reactions. Toxicity of the Tweens has also been shown by animal feeding tests by Krantz.¹

The Spans can be ingested in comparably large quantities, possessing a nutritional value somewhat less than that of neutral fat.^{23, 26} Injection of 0.5 per cent Span 20 in 10 per cent dextrose solution at a rate of 15 ml per minute in a dog weighing 12 kilograms produced no toxic effect, and no hematologic changes were demonstrated. The emulsifying agents used were Span 20, Asolectin (purified soya phosphatides), and sodium cholate. The injection of the emulsifying agents or of the fat emulsion stabilized by the emulsifying agents produced no fatalities and no apparent toxic effects under the conditions of these experiments. The appetites of these experimental animals were unaffected by the injections.

Diminution in blood pressure in experimental animals following intravenous injection of bile salts has been demonstrated by many investigators.²⁷ The sodium cholate present in the emulsifying agents and fat emulsion failed to cause any such change. Obviously the fall of blood pressure following bile salts injection depends on the amount and concentration given and on the rate of injection.²⁸ Fat emulsion injected at 1.5 cc per minute or 0.125 cc per kilogram per minute caused no fall of blood pressure. This is due to the fact that the injection was given slowly with a comparatively low concentration of sodium cholate. The sodium cholate given was probably eliminated from the circulation in a short period of time.^{27, 29}

The cause of the increase of bile flow was probably the presence of sodium cholate since the choleretic effect of bile salts is well known.^{2, 28} There was little change in urine flow, although one might expect some diuretic effect even with this amount of fluid or dextrose. Nevertheless it is important to point out that injection of fat emulsion or of emulsifying agents demonstrated no harmful effect on the mechanism of urine secretion.

The increase of lymph flow in the various groups of experimental animals was probably due to the hypertonic sugar solution in which the fat was contained. Even 0.9 per cent saline by vein or water by mouth increased the thoracic duct lymph flow as shown by Watkins and Fulton³⁰ and Ciandall and associates.¹

The increase of total lipid output and lipid concentration of thoracic duct lymph may simply be due to the lymphagogue effect of these solutions as already discussed or to transportation of some of the injected fat to the lymph or to both. Reinhardt and co-workers³² recovered 9 to 20 per cent of the intravenous radiophospholipids in the thoracic duct lymph after three to six hours. The mechanism and route of this transportation are obscure. It might be transported directly by way of the blood capillaries → tissue spaces → lymph capillaries and

to the lymph, or indirectly by way of the intestine where it would be hydrolyzed reabsorbed, resynthesized, passed into the lacteals and would finally reach the thoracic duct. However, the intestinal lacteals never appeared milky in six dogs during injection of fat emulsion which is evidence against the indirect way of transportation.

Some of the immediate toxic effects were salivation, pallor of tongue and mucous membranes, vomiting, and defecation, usually produced during the injection of fat emulsion and of emulsifying agents if the injection was given beyond 1.5 ml per minute, especially in those animals receiving the first injection. On the other hand, some of the animals would not show this group of reactions even if the injection rate was 2 to 2.5 ml per minute. Obviously there is individual difference in tolerating the fat emulsion or emulsifying agents. The mechanism responsible for producing these reactions is not well understood. Nevertheless the reactions can be prevented if the rate of injection is carefully controlled.

Secondary anemia was produced following the intravenous injection of fat emulsion in the experimental dogs of Dunham and Brunschwig,⁵ McKibbin and associates,^{6b, 4c} and our previous studies.⁷ No investigators have discussed the cause of such anemia following fat emulsion injection in detail. Johnson and co-workers³³ and others³⁴ reported the destruction of red blood cells after fat ingestion. In their experiments they found that the lymph of the thoracic duct of dogs fed fat was markedly hemolytic. They further showed in animals that the daily excretion of the degradation products of hemoglobin was greater on a high fat diet than on one low in fat. The results of Johnson and co-workers³³ led Dunham and Brunschwig⁵ to conclude that the production of secondary anemia in their fat infused dogs was similar to the anemia of the dogs fed a high fat diet.

In the present study, as Tables VII and VIII showed mild anemia was produced in Dogs 4A and 4B, the animals injected with emulsifying agents and Dog 9 one animal injected with fat. These results may be explained by several possibilities.

(1) Lecithin itself (present in the purified soya phosphatides used as one of the three emulsifying agents) or its derivative might be the agent causing hemolysis. According to Lee and Tsai³ approximately 17 mg per cent of lecithin in physiologic saline solution is strongly hemolytic. In the present study, 128 mg per kilogram of soya phosphatides were given with each injection. The relatively slight increase in the lipid phosphorus of the plasma during or following injection indicates that the injected phosphatides are rapidly removed from the circulation.

(2) Sodium cholate used as one of the three emulsifying agents might be partially responsible for the anemia observed in three animals since it is well known that bile salts are hemolytic agents.^{27, 28} The minimum concentration of sodium cholate in plasma necessary to cause hemolysis both in vivo and in vitro is not available. The amount of sodium cholate given (31.5 mg per kilogram) probably would not build up a concentration in the blood stream sufficient to be hemolytic.

(3) Infection was probably the main if not the only cause of anemia in the dogs infused with emulsifying agent (Dogs 4A and 4B), since the reduction of hemoglobin and red cell counts and the elevation of white cell counts were coincident with the application of plastic tubing which caused phlebitis at the site of injection.

The accumulation of fat in the liver observed in Dog 7 following fat injection was not observed in other experimental animals, including both those given emulsifying agents and those receiving fat. The extent to which the liver contributes to the removal of intravenously injected fat remains to be studied, but it is reasonable to suppose that this organ takes up injected fat because of its role in fat metabolism and as the site of reticulo-endothelial tissue. In Dog 7 the serum phosphatase and dye clearance were not altered, and there was no sugar or albumin detected in the urine throughout the four week injection period. There was no evidence of impaired liver function other than the moderate increase in stainable fat, which suggests some delay in metabolism or transport. Probably impaired liver function should be a contraindication to the intravenous injection of fat.

The gain in body weight of Dogs 7, 8, and 9 during the period of fat injection was approximately the same as during the control period, when the same number of calories was ingested. Such experiments furnish no direct proof of fat utilization. The number of calories fed was in excess of that required for maintenance inasmuch as a weight gain occurred. This increase was probably due to fat deposition since there was no evidence of edema. The injected fat was not excreted in the urine or feces. According to the experimental evidences presented by McKibbin and associates,⁶⁰ injected coconut oil was metabolized in the body rather than stored, as judged by the iodine and saponification numbers of depot fat.

The protein-sparing action of fat is in dispute. Forbes and Swift⁶¹ found that protein could be spared by adding lipid to the complete basal diet fed to their albino rats. The evidences of protein sparing action of fat are increased heat production, CO_2 production, O_2 utilization, and decreased urinary nitrogen output. On the other hand, Rappoport³⁷ states that the protein sparing action of carbohydrate is twice as great as that of an isodynamic quantity of fat. The output of creatinine falls below the starving level on a carbohydrate diet, but rises above it on a fat diet. Thus the nitrogen balance alone may not be very dependable in judging the utilization of the injected fat. However, the nitrogen balance during the infusion period was apparently the same as that for the control period while fat was given by mouth. The similarity of data for periods of ingestion and injection suggests but does not prove that the infused fat is utilized as well as that ingested.

The increase of serum lipids following fat injection is as one might expect. The relative increase of the total fatty acids, phospholipids, and total cholesterol was largely due to the relative amount of the individual substance contained in the fat emulsion. According to analysis, the fat emulsion contained 10.66 per cent of total fatty acids, 0.475 per cent of phospholipids, and 0.028 per cent of total cholesterol.

The complete disappearance of the injected fat from the blood stream is demonstrated in this experiment, took not more than seventeen hours and probably required considerably less time as judged by the decrease that occurred during the first four hours after injection. For example the serum lipids of Dog 4A were not far from the control level four hours after injection. These results are similar to the previous reports in regard to the disappearance of the hpenia following intravenous fat injection^{2, 3, 38}. Little and associates³⁹ injected a patient intravenously with 1000 ml of chyle which contained 31 (m per cent of total lipids. The chylous fat disappeared from the blood circulation rapidly as indicated by the plasma lipids determination.

SUMMARY

Stable fine fat emulsions were prepared using Span 20 (0.5 per cent), Asolectin (0.4 per cent), and sodium cholate (0.1 per cent) as emulsifying agents homogenized with refined butter oil (10 per cent) by means of a high pressure Viscolizer.

Fat emulsions (in five dogs) and emulsifying agents alone (in three dogs) caused no fall in blood pressure. In the same animals urine and bile secretions were increased.

The thoracic duct lymph flow increased following injection of fat emulsion emulsifying agents, and 10 per cent dextrose solution. The total output of lymph lipids was increased following injection of fat emulsion but not following the emulsifying agents.

The daily intravenous infusion of emulsifying agents to dogs for four weeks failed to reveal toxic effects.

The daily intravenous infusion of 10 per cent butter oil emulsions to dogs fed a fat free diet resulted in further gain in weight and positive nitrogen balance similar to that of the control period.

Serum total fatty acids were markedly increased following fat injection. The increase of serum total cholesterol and phospholipids was comparatively slight. The serum lipids disappeared from the blood stream within seventeen hours after injection. No appreciable increase of serum lipids resulted following infusion of emulsifying agents alone.

Histologic examinations of the liver and kidney of dogs infused with the emulsifying agents showed normal structures. Of two fat infused dogs one showed essentially normal lungs, liver and kidney while the other showed fat granules in the liver cells.

HEMOPHILIA CURRENT THEORIES AND SUCCESSFUL MEDICAL MANAGEMENT IN TRAUMATIC AND SURGICAL CRISES*

CLAUDE-STARR WRIGHT, M D, CHARLES A DOAN, M D,
VERNE A DODD, M D, AND JAMES D THOMAS, M D
COLUMBUS, OHIO

IN REVIEWING the therapeutic management of forty-three patients with hemophilia observed over the past seventeen years in this Clinic, three more or less distinct periods can be recognized (1) The first was characterized by the use of a succession of nonspecific measures most of which were aimed toward increasing the available circulating thromboplastin. These included snake venom, ovarian hormones, placental extracts, and foreign protein sensitization, with horse serum or egg albumin as antigens. (2) Despite the use of these measures the continuing necessity for supportive, replacement blood transfusions during acute hemophilic bleeding episodes finally led to the recognition that whole fresh blood produced the most effective, even though transitory, reduction in the prolonged coagulation time of any measure then advocated. That fresh or frozen normal human plasma are just as effective as whole fresh blood was demonstrated shortly thereafter. (3) World War II gave a tremendous impetus to the chemical partition, isolation, and therapeutic study of particular fractions from human and bovine blood plasma. As a by-product of these important researches has come a so called antihemophilic fraction of human plasma ushering in a third era which is bringing new hope and optimism not only for the better clinical management of hemophilia, but also for the ultimate solution of the still enigmatic problem of the pathologic physiology and precise biochemistry of this dramatic familial disease entity.

Many theories have been evolved in the attempt to explain the abnormal coagulation mechanism of hemophilia. Most investigators agree that the primary impediment is in the retardation of the conversion time of prothrombin to thrombin. Calcium and a thromboplastic substance are necessary for this reaction. In analyzing the prevailing concepts, common accord is attained only in the fact that there is a lack of available circulating thromboplastin. The divergence of opinion is in the source and/or regulation of this catalytic or stoichiometric agent. Many substances have been demonstrated to have thromboplastic action. Extracts of nearly all animal organs—brain, lung, thymus, testis, muscle, and diffuse connective tissue¹—show varying degrees of this activity. The ubiquity of tissue thromboplastin can be readily demonstrated in determining the clotting time in the hemophilic person. If a clean venepuncture is not obtained, allow-

•The plasma fraction I of Cohn used in this study was prepared from blood cells of from voluntary donors by the American Red Cross. This is one of a series of investigations in hemophilia being carried out with material supplied by the American National Red Cross. As soon as sufficient data become available to justify final conclusions concerning its therapeutic value a full report to the medical profession on the use of this plasma fraction in medical practice will be published.

only minute amounts of tissue juice to admix with venous blood a false lowering of the coagulation reading results. Proteolytic enzymes, Russell viper venom, saliva,² and, recently, urinary extracts⁴ penicillin, streptomycin⁵ and the products of roentgen radiation⁶ have been shown to function directly or indirectly as thromboplastic agents.

Lysed platelets have long been known as one of the most potent sources of thromboplastin.¹ Therefore interest for many years has been focused on the possible functional abnormality or inadequacy of hemophilic platelets. Howell and Cekada⁷ supported this concept, citing the observation that platelets from the hemophilic person fail to agglutinate readily *in vitro* and appear to resist prompt disintegration, thereby delaying presumably the liberation of their known thromboplastic content with a resultant prolongation of blood coagulation. Brinkhous⁸ has recently presented data suggesting that a plasma factor is involved in the release of thromboplastin from platelets a factor deficient in the hemophilic patient. Quick,⁹ however, indicates that the hemophilic defect may be due to the lack of a thromboplastin precursor which is quantitatively adequate in normal blood and is activated to thromboplastin by an enzyme from lysed platelets.

Ferguson hypothesizes that hemophilia is due to a deficiency in available trypsin, which according to his enzyme theory of coagulation is necessary for the conversion of protbrombin to thrombin.¹⁰ It has been adequately demonstrated that trypsin both *in vivo* and *in vitro* will shorten the clotting time of hemophilic blood, albeit *in vivo* it is a rather hazardous procedure.¹¹

As the cause of delayed blood coagulation in the hemophilic person and in contrast to the theory of thromboplastin deficiency. Toeautins¹ ¹² ascribes this phenomenon to an excess of circulating anticoagulant, so called anticephalin an antithromboplastic substance. In support of these conclusions he has accumulated a series of well controlled experiments.

Another of the hypotheses based on the lack of an essential circulating coagulation factor has evolved from the well known fact already stated, that the administration of fresh whole blood or plasma from a normal person will shorten the coagulation time in the hemophilic person whereas plasma or blood from another hemophilic patient is ineffective. Studies over the past eleven years at the Thorndyke Memorial Laboratory have resulted in the separation of a globulin from normal plasma capable of accelerating clot formation in the hemophilic subject.¹⁴ ²¹ Under the direction of Dr. Edwin J. Cohn* and as part of the war research plasma fractionation program, whole human plasma was separated on a physicochemical basis into five major portions.²² The antihemophilic property was found to be most potent in fraction I which also contains fibrinogen. Fraction I separated from hemophilic plasma has been shown to be lacking in this specific activity.¹⁹ This antihemophilic fraction now has been prepared from surplus pooled blood plasma in sufficient quantities for clinical evaluation and reports of the therapeutic effectiveness of this fraction are beginning to accumulate.¹⁷ ²³

CLINICAL STUDIES

Upon the demobilization of the Civilian Defense Program a supply of frozen human plasma was placed at our disposal for investigative purposes. These non-pooled units of 250 cc each were prepared by the prompt separation of all cellular elements, followed by rapid freezing of the whole plasma within a few hours after blood withdrawal from the donor according to the technique of Strumia, McGraw, and Reichel²⁴. In the frozen state the antihemophilic activity of normal human plasma remains potent indefinitely and is readily available on rapid thawing in a water bath at 37° C, thus providing a convenient and effective therapeutic supply of the antihemophilic principle. Lyophilized plasma prepared within a few hours after withdrawal from the donor has been reported to be as effective as the original plasma²⁵. This activity of thawed plasma, however, diminishes rapidly after several days' storage at 4° C. This loss of antihemophilic activity during storage of plasma in the liquid state has been reported by others^{26, 27}. Similar rapid diminution of the antihemophilic principle has been observed *in vivo*, the activity lasting a maximum of not more than seventy-two hours, irrespective of the amount given. The duration of activity above certain amounts appears to be exponential²⁸. (This of course varies with the degree of the coagulation defect in the individual patient. On the basis of repeated observations in severe hemophilic subjects, the maximum duration of effect usually can be obtained with 50 to 100 cc of fresh plasma or restored frozen plasma.)

Studies with the concentrated antihemophilic fraction of Cohn were initiated in this Clinic early in 1946 when material for clinical studies was made available*. Certain selected cases from our clinical studies are presented to illustrate (1) the comparative effectiveness of the antihemophilic fraction I of Cohn versus freshly thawed plasma in promoting clot formation and (2) the possibility of successful medical management of the hemophilic patient during both elective and emergency surgery.

The Antihemophilic Activity of Plasma Fraction I—

CASE 1—(Fig 1) At the time when the first supplies of plasma fraction I of Cohn were received, we were studying the effect of varying amounts of freshly thawed frozen plasma on a 17 year old hemophilic subject (Patient L. B.) who had been admitted for treatment of a large ulcerating lesion on the posterior surface of the right thigh, caused by the sloughing of a massive spontaneous intramuscular hemorrhage several months before. The comparative studies of plasma fraction I and freshly thawed frozen whole plasma are graphed in Fig 1.

The intravenous administration of 50 cc of freshly thawed (at 37°) frozen plasma brought an immediate fall in the coagulation time to normal values, which were maintained for twenty-four hours. Sixty hours later the coagulation time had returned to the prolonged base line values. Two units of fraction I (equivalent to 0.4 Gm of prothrombin dissolved in 10 cc of distilled water, were injected intravenously over a five minute period. This reduced the coagulation time to normal but held for less than four hours. Four units administered intravenously approximated the activity of 50 cc of thawed whole plasma.

*Through the courtesy of Dr. Louis Diamond and later through the Medical Administration Committee, American National Red Cross.

†Coagulation times were determined in the following manner: 1 cc of venous blood were aspirated into a dry syringe, noting the time the blood first entered the syringe. A 1 cc cubic centimeter was then injected into each of three dry test tubes with an 8 mm. internal diameter; the fourth cubic centimeter was discarded. The first and second tubes were examined at intervals for clot formation. Coagulation of the third tube was accepted as the end point. (Normal 10 to 30 minutes.)

It is of some interest that, in a number of instances in which a study was made of this type of single injection titration, the coagulation time rebounded to higher than the original base line levels, producing a biphasic curve.

CASE 2—(Fig. 2) M S, a 5 year old boy, had received freshly thawed frozen plasma and whole blood at frequent intervals over two and one year years for the control

Fig. 1.—Case 1 Comparative effectiveness of plasma fraction I of Cohn against restored frozen plasma in the control of the coagulation defect in hemophilia

Fig. 2—Case The rapidly progressing hemorrhage into the subcutaneous tissues of the neck was checked by the control of the prolonged coagulation time with intravenous plasma fraction I of Cohn. Two days later transfusion of fresh whole blood alleviated the anemia as well as continued the maintenance of a normal coagulation time. Note comparative effectiveness of 0.1 Gm. of plasma fraction I of Cohn 10 cc and 50 c.c. of restored frozen plasma resulting in control of the coagulation time for sixty three twenty four thirty-one and sixty six hours respectively. The duration of effective control of the coagulation time with quantities of restored frozen plasma greater than 50 c.c. is apparently exponential.

of recurrent spontaneous hemorrhages. A maternal first cousin and great uncle were known hemophilic patients. This admission, the ninth, was precipitated by injuries to the right ankle and the left posterior cervical region resulting in the marked subcutaneous ecchymoses which had been progressive over the three days preceding hospitalization. There was a marked hematoma involving the entire left side of the neck, measuring about 13 cm. in diameter and extending from the surface plane of the neck approximately 8 cm., resulting in a fixation of the neck and head to the right. Ecchymoses were scattered over the entire body and extremities.

The initial coagulation time was 50 minutes. Cohn's fraction I, 0.2 Gm intravenously, brought about an immediate lowering of the coagulation time to 13 minutes. To ameliorate the severe posthemorrhagic anemia, the patient was given a transfusion of 500 cc of fresh whole blood, thus lowering the coagulation time from 32 to 8 minutes, normal coagulation being maintained for over sixty five hours. A rebound to over four hours was corrected with 0.1 Gm of Cohn's fraction I. Additional titration studies with increasing amounts of freshly thawed frozen plasma continued to maintain the coagulation time within the range of normality. Clinically there was clearing of the cervical hematoma to the extent that at the time of discharge there was only a small resolving surface ecchymotic area remaining.

The release of an increased quantity of antihemophilic globulin* is allowing currently a more extensive clinical evaluation in a number of clinics. The excellent responses obtained during acute hemorrhagic crises in this as well as other clinics is encouraging.

Surgery and the Hemophilic Patient—Only in the last few years has even minor surgery in the hemophilic patient been undertaken without fear and trepidation. With a clearer understanding of the coagulation defect and with materials available for control, it is now possible to accomplish successfully major surgical procedures. Two illustrative case studies are presented.

CASE 3—(Figs 3 and 4). A. H., a 24 year old Mennonite farmer, walked into the emergency room of University Hospital apparently uninjured superficially following an automobile accident. Two companions appeared to be more seriously injured and immediate attention was shown them. The attending surgeon (V. A. D.), however, noticed the sudden development of diaphoresis and pallor in the first man and upon further questioning elicited complaints of increasing weakness and pain in the upper left abdominal quadrant. Examination revealed a small, superficial, bruised area at the costal margin, a rigid abdomen, and a state of imminent constitutional shock. The patient then informed the surgeon that he and other male members of his family had been under our observation for several years for hemophilia. A tentative diagnosis of traumatic rupture of the spleen was made, plasma transfusions were started immediately and simultaneously in both arms. Emergency surgical exploration revealed an abdomen full of free blood, its source being a small laceration at the inferior pole on the posterior surface of the spleen. Splenectomy was successfully accomplished and during the first twenty five hours the patient received 14 units of plasma (3,500 cc) and 4 units of whole blood (2,000 cc). On the second hospital day the coagulation time was 6 minutes. By the third hospital day, despite the tremendous quantities of borrowed blood and plasma, it had increased to 50 minutes, and oozing about the incision resulted in the loss of approximately 500 cc of blood. Thereafter daily transfusions of whole blood and/or fresh plasma were given, administered so as to maintain the coagulation index at all times under 30 minutes. Control of the hemophilic bleeding during the remaining period of convalescence was satisfactory and no further complications developed.

The genealogic history (Fig 4) revealed that both maternal and paternal grandfathers of the patient had been hemophilic. On the maternal side the patient had ten

HEMOPHILIA Genealogic History

0-6929 A.H. ♂ Aged 24 yrs

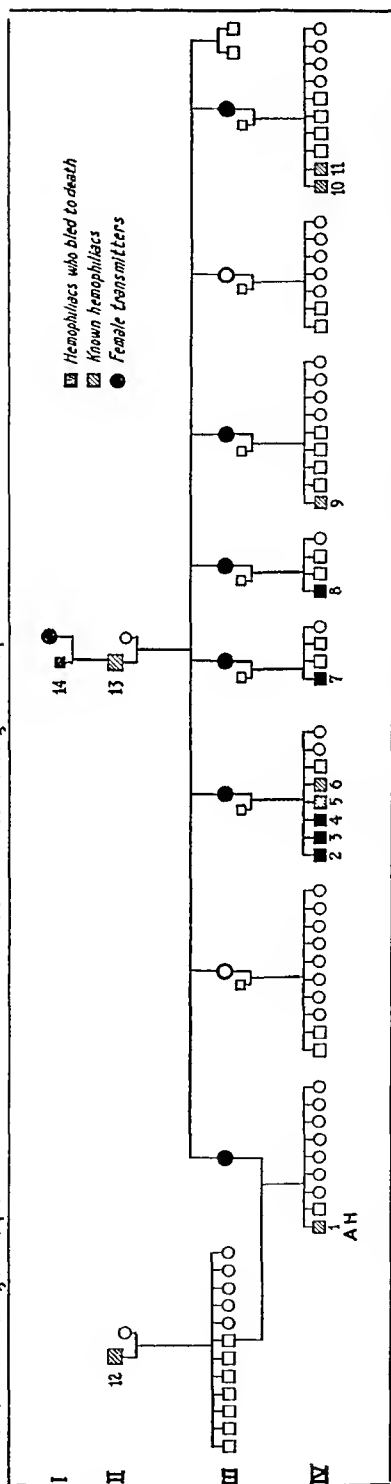

Fig. 4.—Genealogic history of Patient A. H. (Case 3) 1, whose hematologic data are elicited in Fig. 3. Five of ten hemophiliac cousins died from complications of hemophilia. 2 died nine days post appendectomy age 27, 3 died from internal hemorrhage following injury while loading wheat age 23, 4 died following hemorrhage from leg ulcer age 23, 5, a moderate bleeder age 43, was studied in this clinic and examination times were controlled with restored frozen plasma for tooth extractions. 6, a moderate bleeder age 7, died from hemorrhage following tooth extraction age 21, 8 died from hemorrhage following tonsillectomy age 20, 9 moderate bleeder age 28, 10, moderate bleeder appendectomy four years ago severe postoperative bleeding controlled with fresh blood, 11, severe bleeder, 12 the paternal grandfather was a severe bleeder, 13 maternal grandfather was a moderate bleeder, 14 a maternal great grandfather died to death following slight trauma.

CASE 4—(Fig 5) G F, a 26 year old white man, had experienced severe alveolar pain for eight months preceding his first admission to University Hospital. The patient had consulted several dentists for extraction of the diseased teeth but had been refused attention due to a severe hemophilic diathesis which had resulted in recurrent crippling hemarthroses since his fifth year of age. Profuse bleeding followed a tooth extraction at the age of 8 years. The alveolar pain was so severe and constant that for four months the patient had required Dilaudid, 4 mg every four hours. The initial coagulation time on admission was 125 minutes. Coagulation studies were made over a forty eight hour period preliminary to dental surgery. Comparatively frequent doses of freshly thawed frozen plasma were necessary to bring and keep the coagulation time within or near the range of normality. Determinations of the coagulation time were made three times daily and whenever values were on the upward trend additional plasma was administered. On the third hospital day, after receiving 250 cc of plasma preoperatively, extensive dental surgery* was accomplished. The extraction required removal of a moderate amount of osseous mandibular tissue. Practically no hemorrhage occurred during the operative procedure. Throughout convalescence only minimal oozing from the operative site, normal for the degree and extent of the surgery, was evident.

Fig 5.—Case 4. A forty eight hour control study preceding surgery indicated the expected response of the coagulation defect to restored frozen plasma. Extensive dental surgery was required to extract an impacted molar tooth. Operative and postoperative bleeding was minimal. Therapy continued for eight days. Two days after discharge trauma to granulating socket initiated hemorrhage requiring readmission. Coagulation time was 45 minutes. Additional plasma therapy controlled hemorrhage satisfactorily.

Rigid control of the coagulation mechanism was continued for six days postoperatively. Up to the time of discharge there was no hemorrhage. Two days later the patient inadvertently traumatized the oral granulating surface at the site of extraction with resultant profuse bleeding. Upon readmission the coagulation time was 45 minutes. Administration of freshly thawed frozen plasma again satisfactorily controlled the hemorrhage and convalescence was completed without further complications. The patient has since had another tooth extraction which was successfully managed under a similar regime.

DISCUSSION

Why does the hemophilic person bleed? Is it an inherent increased instability of the platelets? Is it an excess of an antithromboplastic substance? Is it a defect in trypsin, in a thromboplastic precursor, in antihemophilic globulin?

Most of the evidence in support of these hypotheses adds up to a *post hoc, ergo propter hoc* order of reasoning, and in examining one without consideration of the others, each is presented with convincing evidence and a good case is made. The ultimate solution may well represent a compromise between the presently held individual hypotheses.

The diagnosis of true hemophilia not infrequently presents a real problem. The classic criteria include (1) a familial history of the symptoms of hemophilia, (2) a personal history of more or less difficulty in controlling hemorrhage, especially following trauma, and (3) the demonstration of a prolonged coagulation time of venous blood. Recently, the demonstrable shortening of the coagulation time after parenteral administration of one of the antihemophilic globulins containing substances has proved to be a valuable confirmatory therapeutic test. Strange as it may seem, the differential diagnosis of hemophilia from other hemorrhagic diatheses, as for example thrombocytopenic purpura or hypoprothrombinemia, is not always immediately possible in an individual who is in a clinical remission at the time of examination. Vacillations in the clinical manifestations of either purpura or hemophilia reflect differences in the severity of the thrombocytopenia or the degree of prolongation of the coagulation time, respectively, from time to time (Fig. 3). A series of laboratory studies over a period of days, or even months, is occasionally necessary to establish a diagnosis. This type of study was necessary in a young physician who had experienced recurrent hemorrhagic episodes since infancy. A maternal uncle had been a bleeder. Both hemophilia and purpura had been clinically diagnosed at different times and in different clinics, though all previous coagulation studies had failed to show any abnormality and the platelets always had been found to be adequate in number. It was necessary to make serial daily studies of all phases of the coagulation mechanism. On only two of five consecutive days was a prolonged coagulation time found upon which to establish a hemophilic diathesis. Six months later an acute appendix was successfully removed under a regime of rigid coagulation time control. A similar study over a six month period was recently necessary in an 8-year-old youth to establish a recurrent thrombocytopenia as the definitive cause of hemorrhagic difficulties rather than a previously diagnosed hemophilia. *It is important that these fluctuations in the various factors of the coagulation mechanism from time to time be recognized, so that, if the specific abnormality or defect is not clearly defined and apparent on a single examination, repeated studies, particularly at the time of recurrence of symptoms, will be made.*

A rational approach to the successful therapeutic management of hemophilia must include three avenues: first, the use of specific therapeutic agents to promote coagulation of the blood per se, second, the institution of a prevention and guidance program through training the child with hemophilia in early life to adapt himself to and accept the various limitations enforced by the disease, and third, intelligent utilization of the physical therapist in overcoming the otherwise frequently crippling hemarthroses.

Control of acute hemorrhage in the hemophilic person is approached from two angles: prompt parenteral therapy in maintaining a normal coagulation

time for the duration of the emergency, and the local application of hemostatic agents where indicated and when possible

The active antihemophilic principle present in nonhemophilic blood is preserved only under certain conditions. The activity deteriorates rapidly under most *in vitro* conditions, therefore whole blood or plasma only when relatively fresh is effective. The coagulation promoting activity may be preserved by freezing or lyophilizing plasma within a few hours after withdrawal from the donor. Restitution of frozen plasma requires rapid thawing in a water bath at 37°, otherwise denaturation of the plasma proteins may occur with precipitate formation. Both properly prepared frozen plasma and lyophilized plasma provide excellent permanent, readily available sources of antihemophilic substance. The concentrated unit of powdered plasma fraction I of Cohn is rehydrated with distilled water and has a protein equivalent of 60 to 75 cc of plasma, with an antihemophilic activity of ten to fifteen times the comparable volume of plasma from which it came.⁹ The fraction was prepared from blood which had been held as long as seventy-two hours before the separation of the cells and plasma had been accomplished. Greater potency would probably be obtained from fresh plasma preserved in the frozen state until fractionation. Intravenous or intramarrow administration has proved to be more reliable in reducing the coagulation time than administration by the intramuscular route.

The severity of the hemophilia governs the quantity and frequency of antihemophilic substance. If there is evidence of appreciable blood loss fresh whole blood will provide not only the antihemophilic substance but also replace the loss in red blood cells (see Fig 2). Fifty cubic centimeters of fresh, re-stored frozen or lyophilized plasma intravenously usually will maintain the coagulation time in a moderately severe hemophilic condition within safe limits for about twenty-four hours. One unit of Cohn's plasma fraction I (equivalent to 0.2 Gm protein) will accomplish the same for from three to sixty-five hours. In the hemophilic child the intravenous administration of these materials frequently presents a real problem when most of the available veins have been obliterated by numerous previous venoclyses. The intratibial or intrasternal routes have proved to be quite satisfactory in these instances.

A single venoclysis is generally all that is necessary for the immediate control of an acute hemorrhagic episode, for it is actually only necessary for the coagulation time to remain within normal values sufficiently long for a coagulum to form within the lumen of the hemorrhaging vessels. In the surgical patient it is advisable to have frequent determinations of the coagulation time preferably three times daily. In the presence of ascending values exceeding the upper limits of normal, further therapy for reducing the coagulation time is at once indicated (see Figs 3 and 5). Two to three days study of the relative ease or difficulty of control of the coagulation mechanism in the individual patient is desirable preliminary to elective surgery. Post-operative control is continued for from two to ten days depending on the severity of the hemophilia and the extent of the surgery.

In most instances parenteral control of the coagulation defect will suffice. However it is frequently desirable as an additional precautionary measure to employ local hemostatic agents at the operative site. Fibrin foam and thrombin have proved most effective. In the past, electrocauterization, gelatin, oxy cellulose, placental globulin, epinephrine, viper venom, muscle extracts, and globulin from human, bovine, rabbit and swine sources in addition to mechanical pressure aids have been used with varying degrees of success.

The rare development of a refractoriness in the lowering of the coagulation time by fresh whole blood, plasma, or the plasma fraction I of Cohn after repeated administrations has been observed.³⁰⁻³³ This phenomenon has not been observed in this Clinic. Moderate fluctuations in the coagulation defect are the rule when individual cases are followed over long periods. Depending on the theory of the pathologic physiology to which one subscribes, this may be due to a vacillating quantity of antihemophilic globulin, anticephalin, thromboplastic precursor, or trypsin. It is conceivable that accentuations of these normal fluctuations may play an important role in the refractory states. The demonstration of an anticoagulant associated with the plasma globulin has been reported in several instances.³¹⁻³³ That the developing anticoagulant was an antibody and inhibited or tied up the antihemophilic globulin by means of an antigen antibody reaction has been proposed by Lawrence and Claddock.³¹ Taylor³⁰ and associates have observed a refractory state develop in a patient who had previously responded to fresh whole blood, plasma, and the plasma fraction I of Cohn. Comparatively massive amounts of plasma fraction I of Cohn (10 Gm) and fresh plasma failed to effect significantly the prolonged coagulation time. Only when the greater part of the circulating blood had been replaced by fresh whole blood was normal coagulation again achieved. A similar massive replacement of the circulating blood volume is illustrated in our Case 3 (Fig 3).

The age range of the forty-three hemophilic patients at the time they were first seen in this Clinic is indicated in Table I. Fifteen of this group, or 34.8

TABLE I AGE RANGE OF HEMOPHILIC PATIENTS

AGE (YR)	NUMBER OF PATIENTS
3-5	10
5-10	5
10-20	9
20-30	12
30-40	6
>40	1
Total	43

per cent, were between 3 and 10 years of age. This age group presents the highest incidence of repeated hospitalizations for acute hemorrhagic episodes. The coagulation defect does not appear to be more severe at this age, but normal physical hyperactivity and an immaturity of perception make the child more subject to incidental and accidental trauma with initiation of hemorrhage. Many potential hazards can be overcome by the establishment of hemorrhage management program aimed toward the patient's understanding of and adaptation to his physical limitations. Through the close collaboration and cooperation of the

physician, medical social worker, parents and school authorities, it is usually possible to compromise on an outline of restricted activity which will allow the patient a relatively normal childhood while minimizing the frequency of acute hemorrhagic episodes and thus avoiding the invalid personality that is frequently seen in these patients. The severity of the disease, of course all too frequently dictates its own enforced limitations.

Eleven patients or 25.5 per cent of the group had experienced repeated hemarthroses which had left varying degrees of disability. The severity of the residua frequently totally incapacitated the patient. A program in conjunction with the physical therapist and orthopedist will often provide an opportunity to relieve an otherwise permanent disability. In a joint in which there has been fresh hemorrhage it is possible to aspirate the unclothed blood after control of the coagulation time has been effected with the parenteral use of antihemophilic agents. Physical therapy is administered in both the fresh and old arthroses only when and as the coagulation time is maintained within normal limits. The control of the coagulation time is maintained as outlined for the surgical patient.

CONCLUSIONS

Control of the prolonged coagulation time in the hemophilic patient may be effected by the intravenous or intramuscular administration of (1) fresh whole blood or plasma, (2) reconstituted frozen or lyophilized plasma that has been processed immediately after withdrawal from the donor or (3) the recently separated plasma fraction I of Cohn, a potent antihemophilic substance in our experience.

The temporary correction of the coagulation defect with any of these substances permits in the individual patient with hemophilia both emergency and elective surgical procedures with relative safety.

Physical therapy and carefully controlled orthopedic procedures may be successfully utilized in alleviating the frequently occurring hemarthroses when the coagulation time is maintained within normal values.

The institution of a guidance and prevention program through the cooperation of the physician, medical social worker, parents and school authorities will aid in assisting the hemophilic child to better adapt himself to the limitations enforced by his inherited disease.

EXPERIMENTAL STUDY OF THE COMPARATIVE ACTION OF HEPARIN AND DICUMAROL ON THE IN VIVO CLOT

LEO LOEWF, M.D., EDWARD HIRSCH, M.D., DAVID M. GRAVZEL, M.D.
AND FLORENCE KASHDAN, A.B.
BROOKLYN, N. Y.

IN VIVO experiments concerning the action of heparin on the preformed venous clot have demonstrated its dual action of causing the dissolution of an early thrombus and of stimulating an adequate collateral vasculature by pass to a vein occluded by an organizing clot.¹ In view of the extensive use of dicumarol in venous thromboembolic disease, it was deemed advisable to investigate the action of dicumarol under similar experimental conditions. The purpose of this communication is to record the results of this comparative study and to summarize the literature pertinent to the subject.

METHODS

Experimental venous thrombosis has been obtained by numerous chemical and mechanical methods;²⁻⁶ most of which however are not so completely reliable as to allow for a conclusive statistical survey. Thus the injection of sodium ricinoleate⁶ and crushing of the vein over an intraluminal silk thread⁶ or stretching of the vein⁷ have not proved satisfactory in our hands. The introduction of an extraneous factor in a chemically induced thrombosis complicates the proper evaluation of the anticoagulant to be tested so that we have resorted to a mechanical means of thrombus formation which produced consistent and predictable results.⁸

The genesis and subsequent elaboration of a thrombus depends on any or all of the following factors: stagnation of blood, injury to the intima, local release of relatively large amounts of thrombokinase.

A method utilizing these three factors has been reported elsewhere⁸ and is as follows:

Adult rabbits weighing three kilograms are anesthetized with ether. The jugular veins are exposed and the most proximal portions securely ligated with silk. The distal portion of the vein is held over a narrow strip of metal and firmly struck twenty to thirty times with the handle of a scissors. In about two minutes after bleeding has ceased a palpable and visible clot is usually present. If clotting does not occur, the procedure is repeated. Thrombus formation invariably occurs with this procedure and the clot itself is indistinguishable from the in vivo clot seen in aseptic thrombophlebitis.⁸

Heparinization was effected by means of the heparin/Pitkin Menstruum preparation.^{9, 11*} The Pitkin menstruum is a gelatin base medium which was designed to regulate and retard the release of water soluble drugs incorporated within it. The preparation with varying amounts of heparin has been used extensively on human subjects with consistently satisfactory results. The formulas employed in our experiments contained vasoconstrictors which further delayed the absorption of the heparin and prolonged the effect of a single dose. The dosage has varied from 40 to 100 mg. of heparin given every two to three days. The amount was governed solely by the coagulation time which was maintained at not less than three to four times the normal level. The coagulation time was determined by the Lee-White-Howell method.¹² From previous studies we have found that rabbits react uniformly to the action of heparin.¹ To date we have encountered no heparin resistant rabbits.

Dicumarol was administered by both the oral and parenteral routes. We have found as has Link and associates, that rabbits vary in their response to oral dicumarol but that all

rabbits respond to the intravenous administration of the disodium salt of dicumarol.^{13, 14} However, we have noted that, contrary to the observations of Link, rabbits orally dicumarol sensitive occasionally change in sensitivity so that the intravenous route becomes obligatory. Dicumarol was given orally in 6 mg doses. The disodium salt was prepared according to the procedure of Link¹⁴ and was administered in 12 mg doses. The dosage and the interval between doses was governed essentially by the daily prothrombin time. Dicumarolized animals were fed a diet low in ascorbic acid which has been shown to be an antagonist of dicumarol.¹⁵ In our early experiments, excessive doses of dicumarol caused loss of animals through coma, convulsions, and death. These toxic manifestations agree with the recorded data on the toxicity of this drug.^{16, 19} In no instance have we noted death due to hemorrhage, possibly because of a careful regard for the prothrombin time.

Prothrombin Time—Prothrombin time was determined on the dilute plasma by the Link modification¹³ of Quick's method.²⁰ Fresh thromboplastin was used daily. Prothrombin times were recorded only when two successive determinations agreed within the arbitrary limits of 5 per cent. Sufficient dicumarol was given to maintain the prothrombin time above one and one half times normal, as measured in seconds.

Scope of the Experiment—Thrombosis was induced as described previously. On the ninth and fourteenth days after the induction of thrombosis, heparin or dicumarol was administered to alternate animals, respectively. Sufficient amounts of anticoagulant were given to maintain either the coagulation time or the prothrombin time well above clinically accepted limits. Anticoagulants were administered for two weeks. This arbitrary limit was set by our previous experiments¹ with heparin in which it was shown that the maximum effect was obtainable within that period. At the completion of this period the animals were anesthetized with ether, the veins were inspected, photographed in situ, and sections were taken for microscopic examination. There was no need to obtain control animals since our previous experiments¹ have yielded controls for all periods up to thirty days after the induction of thrombosis.^{1, 5}

RESULTS

The scope and results of the experiment are seen in Tables I and II.

From Table I (anticoagulant therapy started nine days after induction of thrombosis) it may be seen that of the six veins heparinized for two weeks, four were patent (Fig 1) and two were occluded (Fig 2), while in a similar number of dicumarolized veins, two were patent (Fig 3) and four were occluded (Fig 4). All of the control veins were occluded. The visible collateral system appeared to be greater in the heparinized series.

TABLE I FOURTEEN DAYS OF ANTICOAGULATION THERAPY STARTED NINE DAYS AFTER INDUCTION OF THROMBOSIS

	NUMBER OF VEINS	PATENT	OCCLUDED	COLLATERALS
Heparin	6	4	2	++ to +++
Dicumarol	6	2	4	+ to ++
Controls	6	0	6	0 to +

TABLE II FOURTEEN DAYS OF ANTICOAGULANT THERAPY STARTED FOURTEEN DAYS AFTER INDUCTION OF THROMBOSIS

	NUMBER OF VEINS	PATENT	OCCLUDED	COLLATERALS
Heparin	8	6	2 Recanalized	+++ + to +++
Dicumarol	8	2 Patent 2 (Extensive recanalization)	4	
Controls	8	0	8	+

Fig 1.—Rabbit 40B nine days after thrombosis fourteen days of heparin. The lumen is narrow and empty. The internal elastic membrane is well defined. (Elastic van Gieson $\times 80$)

Fig 2.—Rabbit 61C nine days after thrombosis fourteen days of heparin. The lumen is almost completely filled with an organized thrombus. A portion of the original lumen remains. Note that this does not represent recanalization but the original lumen now formed in part by endothelial lined thrombus. (Elastic van Gieson $\times 80$)

Fig 3—Rabbit 63C nine days after thrombosis fourteen days of dicumarol The lumen is patent. The elastica is fragmented. (Elastic van Gieson X80)

Fig 4—Rabbit 62 nine days after thrombosis fourteen days of dicumarol. The lumen is occluded by a thrombus in which areas of sludge formation are still present. Beginning organization is present at one margin. Despite the age of the clot (twenty three days) it presents all the characteristics of an early thrombus. (Elastic van Gieson X30)

Fig 5—Rabbit 31B fourteen days after thrombosis fourteen days of heparin. The lumen is patent. The internal elasticia is reduplicated. (Elastic van Gieson $\times 60$)

Fig 6—Rabbit 59C fourteen days after thrombosis fourteen days of dicumarol. The lumen is contracted but empty. The internal elasticia is markedly fragmented. (Elastic van Gieson $\times 10$)

From Table II (anticoagulant therapy started fourteen days after induction of thrombosis) it is evident that of eight heparinized veins, six were patent microscopically (Fig 5) and two showed extensive recanalization. Of eight clotted veins, two were patent (Fig 6), two showed extensive recanalization, while four were occluded. These last four were considered occluded although they demonstrated recanalization. The recanalization was, however, similar in extent to that of the control veins. The lumina of all the patent veins were markedly narrowed and showed considerable subintimal proliferation. All vessels appeared to be occluded on gross inspection, patency being established by microscopic section. The collaterals were far greater in size and number in the heparinized group.

DISCUSSION

The results which we have recorded represent the inevitable continuation of our investigations into the physiology of the anticoagulants. It would seem proper at this point to review the experimental work on this subject since such an historic survey reveals horizons not ordinarily perceptible to the worker in such a narrow field.

Heparin—With the discovery of heparin by McLearn¹ and its subsequent elaboration by Howell²² the ability of this substance to retard coagulation stimulated many workers to find a suitable application in experimental work with an eye toward the therapeutic value in disorders of blood coagulation. Howell and McDonald²³ demonstrated the innocuousness of the purified material when injected intravenously in dogs and in man and showed at the same time that heparin had no effect on the number of circulating red cells, leucocytes, and platelets. Lack of toxic action of the purified material was demonstrated by Reed²⁴ in several hundred experiments.

The *in vivo* action of heparin differs from the *in vitro* action in which purified reagent is used. Thus, in a mixture of purified fibrinogen and thrombin, heparin has almost no inhibiting action and therefore shows no retarding or blocking effect on the conversion of prothrombin to thrombin.² Heparin is not ordinarily neutralized *in vitro* by thromboplastin.² The *in vivo* action of heparin appears to depend primarily on the combined action of heparin and an undesignated fraction of the serum albumins, the so called albumin X of Quick, in the presence of neutral salts.²⁵ The importance of this factor has been conclusively demonstrated.² Thus, heparin appears to be an antithrombogen, that is an agent which reacts with a constituent in the plasma to form a true antithrombin.^{26, 27} The actual method whereby heparin interferes with the processes of coagulation depends on its very high negative charge. According to Torpes,³⁰ heparin, by virtue of its high sulfuric acid content, contains the strongest electric charge of any high molecular substance in the body. Apparently heparin exerts its action through this charge. This seems to be supported by the neutralizing effect of basic protamine, which has the property of promptly counteracting the action of heparin. The multiple *in vivo* effect of heparin on thromboplastin, prothrombin, and thrombin is more readily explained as a loading and unloading of negative charges on the proteins concerned.

The acknowledged ability of heparin to prevent the coagulation of whole blood by interfering with the formation of thrombin requires no further comment. It is the action on a pure platelet thrombus which appears to be of greater concern. The starting point of such a platelet thrombus is a small mass of agglutinated platelets. The prevention of this clumping is probably the primary action of heparin in the prevention of platelet thrombosis.³¹ Although earlier *in vitro* investigations³¹ revealed that crude heparin was not effective in preventing the agglutination of platelets, subsequent experiments have revealed that in blood to which heparin has been added there has been no clumping of platelets or diminution in their number.³²⁻³⁴ The agglutination of platelets is presumed to be due to an adhesive agent and not to formed fibrin,³⁵ since several workers have been unable to demonstrate the precipitation of

fibrin in white thrombus formation.³⁰ A much higher concentration of heparin is required to prevent the agglutination of platelets than is required to inhibit the coagulation of blood.³¹ Another way of stating this would be to say that although the adhesion of platelets is reduced in the presence of heparin it has been noted that more heparin is required to prevent the agglutination of platelets than to inhibit the formation of fibrin. In rabbit and human blood the platelets of which are either more readily lysed or liberate a more powerful adhesive agent,³² heparin retards but does not completely prevent platelet thrombus formation.³³ With sufficiently large doses of heparin the effect on platelet agglutination develops after a latent period unlike the immediate effect on the clotting time.

The effect of heparin on in vivo thrombi has been studied in three ways.

1 *Action on Thrombi in a Glass Cell or in Cellophane Tub.* Bet and co-workers³⁴ showed that the administration of a large dose of purified heparin prevent or delay the formation of white thrombi in glass cell or cellophane tube interposed between the carotid artery and the jugular vein. It has been similarly shown that when glass cannula are interposed between the cut ends of a large artery adequate heparinization prevents the occlusion of the cannula for periods greater than twenty-four hours while control cannula become occluded after twenty minutes of active blood flow.³⁵

2 *Action on Thrombi in the Coronary Artery.* If the endocardium of the left ventricle of a dog was injured by the injection of sodium ricinolate and the myocardium injured by ligating the anterior descending branch of the left coronary artery large mural thrombi very quickly formed in the lumen of the left ventricle. When however adequate amount of heparin were given before the injury was produced mural thrombi were not seen.³⁶ Similarly it has been shown that coronary thrombi is could be induced by sodium ricinolate injected directly into the coronary vessels in twelve out of thirteen dogs while similar lesion occurred in only one of twelve dogs if heparin was given continuously for twenty-four hours after injury.³⁷

3 *Action on Thrombi in Injured Veins.* Murray Bet and co-workers³⁸ were able to cause intraluminal venous thrombosis by either crushing a vein over an intraluminal silk thread or by the injection of sodium ricinolate into the vein. In either case thrombosis occurred in 80 to 85 per cent of the control. Prophylactic heparinization preceding trauma with subsequent heparinization after trauma resulted in a few minimal thrombi. Heparin administered after trauma maintained the patency of a considerable number of veins. Thus 14 per cent of the control veins remained patent after mechanical trauma while 81 per cent of the test veins retained their patency if heparin was administered for seventy to seventy-two hours. Rabinovitch and Pines induced thrombosis by treating the vein and then causing a partial obstruction to the blood flow by a constricting ligature. The investigators showed that in certain instances heparin cured the disappearance of the thrombi only in the early stages and never when the clot already had been organized.

In an attempt to determine if what stage dissolution of the clot took place and what if any was the action of heparin on the organizing clot we³⁹ induced thrombosis in a manner described earlier in this paper.⁵ Using heparin/Pitman menstruum which would yield a constant anticoagulant effect for at least forty-eight hours, it was found first that patency can be reestablished in a number of veins even as long as six days after a clinically palpable and microscopically acceptable thrombus is present. Second the extent and apparently the speed of recanalization is enhanced by the use of heparin. Third when the vein is so occluded as to preclude the resumption of clinical patency recanalization was still greater in degree and extent under heparin therapy and fourth in the presence of occluded veins which cause definite obstruction to circulation the opening of adjacent collateral venous channels is so extensive in the presence

of heparin that the combined cross-sectional area of the collateral system appears as great as, if not greater than, that of the original vein. We found, in addition, that in every instance of sludge formation such as has been described in experimental frostbite, *Plasmodium knowlesi* malaria and traumatic shock^{44, 45} heparin caused complete solution of the clot with resumption of clinical patency.

Dicumarol—The discovery of the entity known as sweet clover disease by Schofield,⁴⁶ its further elaboration by Roderick,⁴⁷ and finally the magnificent researches of Link and associates^{13, 16, 21, 53} led to the isolation and synthesis of dicumarol, the causative agent of this disease. The physiologic effects of dicumarol as measured by the assay of circulating prothrombin^{13, 20} are too well known to require further elaboration. Animals are presumed not to acquire immunity or increased susceptibility to this hemorrhagic agent¹³ although we have found this not to be absolutely true. However, animals which are insensitive to the oral administration of the drug usually respond to the intravenous administration of the disodium salt of dicumarol.¹⁴ The administration of a single dose effects a reduction of the prothrombin level without producing gross signs of permanent injury. The immediate effects of a massive toxic dose are dyspnea, hyperthermia, vasodilation, convulsions, coma, and death. Since these effects occur within twelve hours, there is no reduction in prothrombin time and consequent no hemorrhage.^{1, 11} The continued feeding of this substance is necessary for the production of hemorrhages.¹⁶

The action of dicumarol is not clearly understood. However, studies indicate that it prolongs the prothrombin time and hence the coagulation time in animals^{17, 54} and in man.⁵⁵ It has been shown that the action of dicumarol influences both the production of fibrinogen and the synthesis of prothrombin.⁵⁶ The thirty-six to forty-eight hour lag in response¹³ corresponds to the time necessary to utilize completely the prothrombin circulating in the blood. Vitamin K⁵⁷ counteracts the anticoagulant effects of dicumarol while vitamin C probably intensifies this protective action of Vitamin K.¹⁶ Dicumarol is ineffective in vitro.¹

Platelet adhesiveness is undoubtedly a factor in thrombosis. Wright⁵⁸ observed an increased stickiness at the time when, statistically, thrombosis is likely to occur. There was a simultaneous increase in the platelet count. She thus postulated that the large numbers of newly formed platelets are hyperadhesive. The same observer noted that the greater the concentration of heparin the less is the stickiness of the platelets.⁵⁸ The adhesiveness of platelets also definitely decreases after dicumarol administration^{33, 61} and bears a direct relationship to the prolongation of the prothrombin time. However, the prothrombin time must be decreased significantly before an actual decrease in platelet adhesiveness can be demonstrated.^{32, 62} Dicumarol causes no appreciable difference in the number of circulating platelets.^{32, 34, 62, 63} Clot retraction is retarded in the presence of sufficient amounts of dicumarol to elevate the prothrombin time significantly.^{36, 57}

The experimental studies concerning the effect of dicumarol on the thrombus and thrombus formation have paralleled the heparin investigations. Experimental intravascular clotting ordinarily does not occur in animals which are under full dicumarol effect.⁶⁴ Glass cannulas interposed between two ends of an artery were seldom occluded when animal had previously received dicumarol. Patency was maintained for six to eight hours if the prothrombin time was elevated above thirty minutes in dogs.⁵⁴ In the glass cell, around artery jugular vein anastomosis,³⁷ Dale and Jaques⁶⁵ have shown that dicumarol appears to be slightly more effective than single doses of heparin in the prevention of thrombosis. This work was predicated, however, on one dose of heparin, the effects of which are known to disappear in a few hours. Richards and Cortell,⁶⁶ using the ricinoleate method of thrombosis,⁶⁶ demonstrated the protective action of dicumarol in the three and six day experimental animal groups; in their series, the incidence of thrombus formation was much less than in the untreated controls. Others⁶³ have shown that the administration of dicumarol decreases considerably the tendency to thrombosis in vena which have been crushed over an intraluminal silk thread. When blood was trapped in portions of the jugular and femoral vein, delayed thrombosis was apparent in dicumarolized dogs. When thrombosis did occur, the clot was softer and more friable than in the control animals.⁵⁴

COMMENT

The experiment which is herein reported represents the logical step in the progressive series of attempts to elucidate the effect of the anticoagulants on the *in vivo* thrombus. Our knowledge thus far indicates that in the presence of heparin all clots undergo solution if they are in the sludge stage. This is not true of dicumarol because of the time lag between the administration of the drug and the effective prolongation of the prothrombin time. However beyond this initial stage both anticoagulants effectively caused resumption of clinical patency in a considerable number of veins which were occluded by clots for four days or longer, even up to two weeks in duration. This effect is at variance with the commonly accepted knowledge of thrombus behavior. We are not at a loss to explain adequately the solution of a thrombus whose individual platelets appear to have lost their microscopic identity. However since it has been pointed out that the agglutination of platelets is due to the presence of an adhesive agent which is not formed fibrin,³ and since some workers have been unable to demonstrate the precipitation of fibrin in white thrombus formation^{3a} it may be presumed that possibly physical or physicochemical factors of which we are as yet unaware play a role. A possible lead in this direction may be derived from studies of the clot resistance in tails of dicumarolized mice.⁶⁷ In this experiment it was thought that the hemorrhagic condition induced by dicumarol might not be based solely on the prolonged coagulation and prothrombin times or on the decreased firmness of the clot but on the marked capillary dilatation. This widening of the vessels may contribute in a purely physical sense to the initially decreased clot resistance. Thus, small areas may break off because of the impact of an increased volume of blood and may lodge elsewhere in the body. Because of the lack of coagulability of the blood, these small emboli retain their minute size are unable to propagate and thus are rendered innocuous regardless of where they may lodge. On the other hand since clotting is essentially a physicochemical process which is theoretically reversible the preponderance of the equation factors directed against clotting, by virtue of the excessive amounts of emulating anticoagulant material (or its physiologic equivalent), may possibly render into solution a clot which has not yet become organized.

Concerning the relative efficacy of heparin and dicumarol we favor the former. Although this may be attributed to our extensive experience with heparin, we nevertheless have found that it is easier to work with (in the Pitkin menstruum), has more predictable anticoagulant levels is safer and requires a less elaborate laboratory check to maintain safe and effective anticoagulation responses. The action of heparin is more prompt as a result of which all clots undergo resolution if they are in the sludge stage. This is not always the case with dicumarol because of the time lag between administration of the drug and effective prolongation of prothrombin time. The degree of collateralization appears greater with heparin.

SUMMARY

The mechanism of clot formation and the blocking action of the anticoagulants heparin and dicumarol are critically reviewed.

A comparative study was made of the properties and merits of heparin and dicumarol. The relative ability of these anticoagulants to (a) prevent clotting (b) resolve thrombi, and (c) promote an effective vascular by-pass was evaluated.

On the basis of this comparative study it would appear that heparin is superior to dicumarol.

THE EFFECT OF DIETHYLSTILBESTROL ON BLOOD LIPIDS AND THE DEVELOPMENT OF ATHEROSCLEROSIS IN CHICKENS ON A NORMAL AND LOW FAT DIET

L. HORLICK,* M.D. AND L. N. KATZ, M.D.
CHICAGO, ILL.

THE occurrence of large cyclic changes in the calcium phosphorus and lipids of the blood in egg laying vertebrates during periods of egg production is a well known phenomenon. The literature bearing on this subject has been amply reviewed by Riddle¹ and by Gardner and Pfeiffer.² The variations are considerable, amounting to a threefold increase in calcium²² phosphorus^{4, 5} and lipids^{6, 26, 28} during the egg laying state. Lorentz, Lutenman and Chaikoff⁶ showed that the increase in the blood lipids consisted of changes in the neutral fat, phospholipid and free cholesterol fractions.

Riddle⁷ was the first to suggest that the ovarian hormone was in all likelihood responsible for this increase in blood calcium phosphorus and lipids in the laying bird. With the advent of estrogenic substances it was found^{8, 9, 24} that administration of these substances resulted in marked increases in the blood calcium phosphorus, and lipids duplicating the changes which occurred cyclically during the egg laying period. These changes can also be induced in the male of the species by the exhibition of estrogenic substances. The changes described have now been observed by many workers using natural and synthetic estrogens given both orally and parenterally.^{10, 13, 2} Gonadotropins also cause an increase in the blood levels of calcium phosphorus and lipids.²³

In 1946, Lindsay, Lorenz, Entenman and Chaikoff¹⁴ reported that they had been able to produce hyperlipemia and atheromatosis in chickens by implanting pellets of diethylstilbestrol. They employed cockerels which were more than 3 months of age at the beginning of the experiment and sacrificed them after six to seven months so that their animals were approximately 9 to 10 months of age at the conclusion of the experiment.

Dauber¹ has shown that spontaneous atherosclerosis occurs in chickens after 5 months of age and becomes increasingly frequent with increasing age of the animals. While the lesions which she described were predominantly in the abdominal portion of the aorta and those described by Lindsay and co-workers¹⁴ were predominantly in the thoracic aorta nevertheless the possibility exists that the results obtained by Lindsay and co-workers may have been due to spontaneous lesions arising because of the age of the chickens at the time they were sacrificed.

Therefore we have repeated the stilboestrol experiment using young birds 6 weeks of age at the beginning of the experiment which were sacrificed when

the birds were approximately 6 to 7 months of age. Thus we attempted to obviate the possibility that the lesions observed were of the spontaneous variety described by Dauber. In addition we investigated the effect of stilboestrol on cockerels maintained on a diet very low in fat and cholesterol. During the course of this study we were able to make observations on the effect of a low fat diet on the blood cholesterol of the chicken and on the occurrence of the spontaneous variety of atherosclerosis in these animals. The latter observations are in the nature of a preliminary report, as the effect of a low fat diet on the occurrence of atherosclerosis is under long-term investigation in our laboratory at the present time.

PROCEDURE

Thirty six white Leghorn cockerels 6 weeks of age at the beginning of the experiment were used. Ten were maintained as controls and received chick starter mash and water ad libitum. An additional six birds were maintained on chick starter mash and water, and pellets of diethylstilbestrol,* 25 mg each, were implanted subcutaneously at the beginning of the experiment and four and eight weeks later. The remaining twenty birds were maintained on a diet of chick starter mash from which fat and cholesterol had been extracted by a commercial degreasing process employing alcohol and ether. The fat content was reduced from 44 per cent to approximately 0.3 per cent†. The extracted mash was dry and powdery, and 8 per cent water was added. To replace the caloric value of the fat removed, 5 per cent sucrose was added¹⁰. To compensate for the destruction of vitamins in the process, supplements were added. The weekly supplements were as follows: vitamin A, 3,600 I.U., vitamin D, 40 A.O.A.C. units, vitamin E, 90 mg, vitamin B, 27 Gm. of brewers' yeast¹¹. The fat soluble vitamins were given in very highly concentrated form in a few drops of cottonseed oil twice a week. The yeast, which contained 5.8 per cent of fat, was mixed with the feed once a week.

Diets of similar composition have been found not to retard the growth of chicks for periods of fourteen weeks¹⁰. Eleven of the twenty birds were maintained as controls and nine received implants of stilboestrol pellets. In three the pellets were not implanted until the animals had been on the low fat diet for almost one month. In the other six, the pellets were implanted at the beginning of the experiment and at four and eight weeks thereafter. Surviving animals were sacrificed when 25 to 30 weeks of age, or after nineteen to twenty four weeks on their respective diets. Hearts and aortas were carefully dissected out and examined grossly for the presence of atheromatous changes. Lesions were graded from 0 to 4 on an empirical basis for severity of atherosclerosis. Several of the aortas were sectioned and examined microscopically. Blood was drawn from the alar vein at three week intervals, and total cholesterol determinations were made by the method of Schoenheimer and Sperry.

*The stilboestrol was generously supplied by Eli Lilly & Company, Indianapolis, Ind.

†We are indebted to The Armour Laboratories, Chicago, Ill. for degreasing large quantities of mash.

‡We are indebted to Lederle Laboratories, Inc., New York, N. Y. for our vitamin supply.

RESULTS

Atherosclerosis of the Aorta—

Normal Controls Ten birds were maintained on chick starter mash and water for periods ranging from two to twenty five weeks. One died after two weeks, one after seventeen weeks, two after eighteen and one half weeks, four

after nineteen weeks and one each after twenty three and one half and twenty five weeks on the plain mash diet. Four of the birds showed gross atheromatous lesions of the aorta. One of the four had a minor lesion in the thoracic aorta (grade ¼), and all four had moderate lesions of the abdominal aorta (grade ½) of the type described by Dukes¹¹ as typical for spontaneous atherosclerosis.

Ordinary Mash Plus Stilboestrol Implants Six birds were maintained on chick starter mash and had three 25 mg pellets of stilboestrol implanted at four week intervals. One animal died after twelve weeks on this diet; the heart and aorta were not examined. One bird died after nineteen weeks and the remaining four were sacrificed after twenty three weeks on this diet. The chicken which died after nineteen weeks of feeding had no lesions of the aorta. The remaining four birds had atheromatous lesions of varying degrees of severity. Three had lesions in both the thoracic and abdominal portions of the aorta

somewhat thickened and showed very fine pin-point yellow deposits in their substance. The brachiocephalic arteries and the thoracic aorta were thickened, and there were elevated yellow patches in both. There was a fine pin point yellow plaque running from the origin of the renal arteries to the bifurcation of the aorta.

Low Fat Diet Controls Eleven chickens were maintained on the low fat diet described. Of these, one died after three weeks and another after eleven weeks on this diet. The remaining birds survived from eighteen and one-half to twenty-three and one-half weeks of feeding. None of the animals in this group showed any evidence of gross atheromatous lesions of the aorta.

Low Fat Diet Plus Stilboestrol Implants Three chickens died early in the course of the experiment, at one, two and one-half, and six weeks of feeding. Three were sacrificed after nineteen weeks of feeding and three after twenty-three weeks of feeding. Five chickens showed atheromatous lesions of the aorta. Of the three chickens which were maintained on the low fat diet for one month prior to implantation of stilboestrol, two showed lesions of the aorta. Of the six in which the implantation was done at the same time that the animals were first placed on the low fat diet, three showed lesions. Two of the six died too early following the implantation to be considered as having had any hypemia as a result of the implantation. Considering the group as a whole, three

birds had lesions in both the thoracic and abdominal aorta and of the other two one had lesions in the thoracic portion and one in the abdominal portion of the aorta. The lesions were slight grading from $\frac{1}{4}$ to 1 and consisted of flat nonraised yellow areas and whitish areas

Summary The low fat control birds showed no gross atherosclerotic lesions of the heart or aortas, while atheromatous lesions were seen in five of the chickens in the low fat, stilboestrol implant group. There were lesions in 80 per cent of the chicks receiving ordinary mash with stilboestrol implants, while 40 per cent of the control birds on ordinary mash and water showed lesions. The lesions in the control group were almost entirely in the abdominal portion of the aorta, whereas those seen in the stilboestrol implanted groups were present in both the thoracic and abdominal aorta and were most prominent in the thoracic portion of the aorta.

Fatty Livers—Fatty livers were observed in two of the animals on the normal diet with stilboestrol implants and in three in the low fat, stilboestrol group. None of the normal controls had a fatty liver, but one of the low fat controls had a very slightly fatty liver.

Body Weight—It was observed that the birds on the normal mash diet with stilboestrol implants were considerably heavier than the normal controls and on autopsy there was a great deal of fat in the tissue depots. The birds on the low fat diet with stilboestrol implants were somewhat lighter than the low fat controls, and both groups were lighter than the normal controls. All birds in the low fat group had very little depot fat.

Blood Cholesterol Levels—In Fig. 1 we have plotted average blood cholesterol levels for the four groups of birds in this experiment. The value for the low fat stilboestrol group is made up of the values from the three birds which were on the low fat diet for one month prior to implantation. It will be seen that these values are higher than those obtained when the implantation was done at the same time that the animals were placed on the low fat diet (Table V).

†Pellets implanted at commencement of low fat diet pellet implantation 5/2, 9/2, 10/2

A possible explanation of this discrepancy is found in the work of Riddle and Senum¹⁰ who found marked fluctuations from day to day in the blood lipids of birds treated with estrogenic substances.

The blood cholesterol levels for the normal control group and for the low fat control group were relatively stable during the experimental period. The latter group tended to show blood cholesterol levels somewhat higher than those for the normal control group. In the stilboestrol implanted birds, the first elevation of blood cholesterol was observed approximately four weeks after the first

Pellet implanted 14 days after four weeks on low fat diet

Pellet implanted at start of low fat diet

implantation of stilboestrol pellets and reached its peak four weeks after the third and last implant. A peak value of 1800 mg. per cent of cholesterol was observed for the normal diet stilboestrol implant birds and of 1300 mg. per cent for the low fat, stilboestrol implant birds. The blood cholesterol fell sharply from the peak values reached and approached normal levels within four weeks.

In summary, the animals maintained on a low fat diet with vitamin supplements showed a tendency to slightly higher blood cholesterol levels than did the control birds. The implantation of stilboestrol pellets resulted in a massive lipemia in birds on a normal and on a low fat diet. The resulting lipemia was greater in the birds on the normal diet. Depleting body fat by maintaining the chickens for one month on a low fat diet prior to implantation of stilboestrol did not interfere with the chickens' ability to show a marked lipemia following the exhibition of the stilboestrol.

DISCUSSION

Our results are in accord with those of other observers who have found that estrogenic substances will result in a massive lipemia and hypercholesterolemia in the egg-laying vertebrates including, in this case, the chicken.^{8,23} We have been able also to confirm unequivocally the report of Chaikoff and co-workers²⁴ concerning the atherosclerogenic action of stilboestrol in the chicken. Although the chickens which we used were younger than those employed by Chaikoff's group, nevertheless 40 per cent of our normal control birds showed the so-called spontaneous atherosclerosis in the aorta. The fact that the stilboestrol-treated birds showed lesions predominantly in the thoracic aorta and that their lesions were more severe than those in the control group makes it clear that the lesions in these birds were due to the action of stilboestrol and were not of the spontaneous type.

We also observed that maintaining birds for a long period of time on a low fat diet did not result in any appreciable lowering of the blood cholesterol below the normal control level for this species. In fact the blood cholesterol of these birds rose to levels slightly above the normal. However it is striking that despite this these birds seemed to be conspicuously free of the spontaneous atherosclerosis seen in control birds fed ordinary mash.

The implantation of stilboestrol pellets in birds on a low fat diet either at the commencement of this diet or after four weeks on the diet resulted in a

massive lipemia only slightly lower than that elicited by stilboestrol in birds on a normal diet. Further, a high proportion of the stilboestrol implanted birds on the low fat diet showed atherosclerotic lesions of an induced nature, whereas the low fat control birds were conspicuously free of atheroma. These findings indicate that it is impossible in the chicken to lower the normal level of blood cholesterol by rigidly excluding cholesterol and fat from the diet. This is in agreement with the work of other observers on the chicken and on man.²¹ Further, the results indicate that under the stimulus of a substance which tended to produce a lipemia, chickens on a low fat diet responded almost as well as those on a normal diet.⁶ Normal chickens which received stilboestrol showed remarkable lipid accumulations in the fat depots. Conversely, both the low fat controls and the low fat, stilboestrol implant birds showed a marked scarcity of body fat. These results indicate that under the stimulus of stilboestrol the chicken can mobilize and store great quantities of fat from ingested fats when available, and probably from carbohydrates and proteins in the diet. When the diet is low in fat, the sources of the lipemia are probably the body stores of lipids, and then the intermediate substances in carbohydrate and protein metabolism. This process is not seriously interfered with by preliminary depletion of fat by means of a low fat diet. Bloch and co-workers^{22, 23} have demonstrated that acetic acid can serve as a precursor for cholesterol and that the site of conversion is most likely in the liver. Thus both carbohydrate and protein can serve as precursors for cholesterol through intermediary substances such as pyruvic acid.

Fleischmann and Friedl¹⁸ have presented evidence to the effect that the estrogen-induced lipemia of chickens can be completely prevented by the simultaneous administration of thyroid substances. They also showed that the total body cholesterol of estrogen-treated chickens is not greater than that of controls. Their experiments were of short duration and hence they were unable to observe the very marked accumulation of depot and body fat which we observed in our stilboestrol implanted chickens on a normal diet. While we did not determine total body cholesterol on these animals, it is highly probable that the cholesterol content of the body, in common with the lipids, was elevated.

Stilboestrol, in the egg laying vertebrates such as the pigeon, duck, sparrow, and chicken and in the egg laying fish and frogs, results in an elevation of the blood cholesterol. It is also generally agreed that the plasma cholesterol of mammals and of women increases during pregnancy. In the pregnant women the increase amounts to 50 to 100 per cent over the nonpregnant concentration.²⁴ Stilboestrol does not have a similar action in the rat.²⁰ Androgenic substances do not appear to have any clear cut effect on the levels of the blood cholesterol.¹⁹

We wish to suggest the possibility that the action of the thyroid substances¹⁹ and estrogens is probably through the liver, by raising or lowering the homeostatic setting for the blood level of cholesterol.²² The liver will maintain this level of blood cholesterol even in the face of a very low intake of dietary cholesterol and fat by synthesizing cholesterol from the other dietary substances. Thus it appears futile to expect that limitation of cholesterol and fat in the diet will lower the normal blood cholesterol level. Furthermore, if abnormal influences are operating to raise the blood level for cholesterol, restriction of cholesterol in

the diet will only partially counter this effect, because of the ability of the body to mobilize and synthesize cholesterol from other sources. Thus we observed a massive lipemia and cholesterolemia and the development of atherosclerosis in animals under the influence of stilboestrol and on a diet very low in fat.

Stilboestrol probably acts to produce atherosclerosis through its cholesterolemic effect. We have previously reported²¹ that in chickens fed cholesterol the occurrence of experimental atherosclerosis is related to the occurrence of a hypercholesterolemia and is roughly proportional in severity to the degree of hypercholesterolemia present. In this experiment the lipemia observed in low fat, stilboestrol implant birds was less than that observed in the control diet stilboestrol implant birds, and the degree of atherosclerosis observed was correspondingly less.

It is of great interest, however, that chickens maintained on a low fat diet and used as controls showed no gross atheroma whatsoever during the experimental period, whereas a group of controls on normal mash showed a 40 per cent incidence of atheromatous lesions. This finding occurred in spite of the fact that the blood cholesterol levels of the low fat birds were slightly higher than those of the normal controls. We do not wish to present this preliminary finding as more than suggestive. Our final conclusion on this point must await termination of the long term, as yet uncompleted experiment now in progress.

SUMMARY

The implantation of stilboestrol pellets resulted in a marked hyperlipemia and hypercholesterolemia in chickens on a normal diet and on a specially prepared low fat diet.

The cholesterolemia observed in the stilboestrol implanted chickens on the normal diet was somewhat higher than that observed in the animals on the low fat diet.

The control animals on the low fat diet showed levels of blood cholesterol slightly higher than those of the normal controls.

Atherosclerosis of the induced type was observed in a high proportion of the stilboestrol treated chickens in both the normal diet and low fat diet groups.

Spontaneous atherosclerosis occurred in 40 per cent of the normal control animals and in none of the controls on the low fat diet.

A concept of the mechanism of stilboestrol action and of the control of the normal blood cholesterol is presented.

We are indebted to the technical staff of the Department who were vital in the execution of this study.

EFFECTS OF TETRAETHYLAMMONIUM CHLORIDE ON BLOOD FLOW IN THE EXTREMITIES OF MAN

OWEN L. SLAUGHTER M.D. * HUGH S. BROWN M.D. * AND
KHAIR G. WAKIM M.D. Ph.D. †
ROCHESTER MINN.

ALTHOUGH the vasodepressor effects of the tetraethylammonium ion had been observed years ago by Marshall¹ and by Trendelenburg² the site of action was not known until recently. Acheson and Moe³ and Acheson and Pereira⁴ in 1946 showed that the drug caused its effect not by action on the heart, vascular smooth muscle, or medullary vasomotor centers, but by blocking the ganglia in the efferent pathways of the sympathetic vasoconstrictor nerves. Acheson and Moe³ measured the blood flow in the femoral artery of the dog by means of a flow cannula and a differential manometer. They found that while the intra-arterial injection of tetraethylammonium chloride caused no increase in blood flow, the intravenous injection caused a marked increase in blood flow. Berry and associates⁵ showed that tetraethylammonium chloride caused a rise of skin temperature in man equal to or greater than that caused by sympathetic block. By the use of the plethysmograph Collier and associates⁶ demonstrated an increase in peripheral blood flow following intravenous administration of tetraethylammonium chloride to patients suffering from various vascular and allied disorders. In one subject the blood flow in the foot increased from 0.24 to 5.2 cc per minute per 100 Gm. of tissue following the intravenous administration of 500 mg. of tetraethylammonium chloride.

The purpose of this study was to determine the effect of tetraethylammonium chloride on the blood flow in the upper and lower extremities of healthy human beings in a relatively warm environment (temperature ranging between 80 and 85°F) and to establish a basis for comparison with subsequent studies on various abnormalities of the vascular system in patients.

Seven healthy young adults, four men and three women whose ages ranged from 22 to 30 years and whose weights ranged from 118 to 190 pounds (53.5 to 86.2 kilograms), were studied. The room temperature varied from day to day between 80 and 85°F but it did not vary more than 1°F, during any single period of observation. The plethysmographs used in this study were those designed by Berry and associates. The plethysmographs were connected to compensating spirometer recorders and blood flow curves were recorded optically. The arm plethysmograph included the hand and forearm to 1 inch (2.5 cm) above the olecranon process, and the leg plethysmograph included the foot and leg to 1 inch below the tibial tuberosity.

The procedure employed in this study was as follows. The subjects were instructed not to eat or smoke for at least ninety minutes before the test. All four extremities were comfortably sealed in the plethysmographs and sufficient time was allowed for adaptation. Control determinations of blood flow were made for twenty to thirty minutes thereafter. Tetraethylammonium chloride was then administered intravenously at the rate of 100 mg per minute. Six individuals were given 300 mg each and one subject, a man weighing 190 pounds, was given 450 mg of tetraethylammonium chloride. The drug was given slowly in order to avoid unpleasant reactions such as precipitous fall in blood pressure, anxiety, and so forth. Blood flow was determined again immediately after completion of the injection and at regular intervals for thirty-five to forty-five minutes thereafter.

Fig 1—Blood flow in the leg before and after intravenous administration of tetraethylammonium chloride

A typical series of blood flow curves from the forearm which are representative of the changes observed in all the extremities is shown in Fig 1. The first curve is a record of control flow, the total flow was 102 cc per minute. The next flow curve was taken five minutes after the injection was started. It shows a blood flow of 314 cc per minute, a significant increase over the control flow. The next two curves were taken at twenty and thirty-five minutes, respectively, after the injection was started, they show a gradual reduction of the augmented flow, but it is still higher than the control value.

The typical response to tetraethylammonium chloride is shown in Fig 2. After the control blood flow was established, 300 mg of the drug were given intravenously. The blood flow increased immediately and reached a maximum about five to six minutes after the injection was started. The flow at the peak

Fig. 1.—Changes in blood flow in the upper and lower extremities as a result of intravenous injection of tetraethylammonium chloride.

of the increase in the leg was 197 per cent higher than the control value. The flow then gradually decreased but even at the end of the observation (thirty five minutes after injection) the flow was still greater than the control.

TABLE I EFFECTS OF INTRAVENOUS ADMINISTRATION OF TETRAETHYLAMMONIUM CHLORIDE ON THE BLOOD FLOW IN THE EXTREMITIES

SUBJECT	FLOW (CC PER 100 CC OF TISSUE PER MIN)				INCREASE IN FLOW (%)		DOSE OF TETRAETHYLAMMONIUM CHLORIDE (MG)
	CONTROL		MAXIMUM AFTER TETRAETHYLAMMONIUM CHLORIDE				
	FOREARM	LEG	FOREARM	LEG	FOREARM	LEG	
1	73	32	147	95	101	197	300
2	17	17	34	51	100	200	300
3		45	--	72	--	60	300
4	47	18	100	40	113	122	300
5	67	38	105	75	57	97	450
6	50	--	110	--	120	--	300
7	40	--	83	--	108	--	300
Average	49	30	97	67	100	135	

The results obtained from study of the seven persons are summarized in Table I. The average blood flow in the forearms of all the subjects before the administration of tetraethylammonium chloride was 49 cc per 100 cc of limb volume per minute, and it ranged from 17 to 73 cubic centimeters. After the injection of tetraethylammonium chloride the blood flow increased in every case. The maximal increase occurred between five and fifteen minutes after injection (average, about nine minutes). In all the subjects the maximal blood flow in the forearms after the injection of tetraethylammonium chloride averaged 97 cc per 100 cc of limb volume per minute and ranged from 34 to 147 cubic centimeters. This represents an average increase of 100 per cent over the control flow,

with a range of increase of 57 to 120 per cent. The control blood flow in the legs, before the administration of tetraethylammonium chloride averaged 30 cc per 100 cc of limb volume per minute and ranged from 17 to 45 cubic centimeters. After injection of the drug, the blood flow in the legs also increased in every case and reached a maximum at the same time as in the arms. The average maximal blood flow in the legs, after injection of tetraethylammonium chloride, was 66 cc per 100 cc of leg volume per minute, the range was from 40 to 95 cubic centimeters. This represents an average increase of 135 per cent over the control value with a range of from 60 to 200 per cent. The increased blood flow in both upper and lower extremities gradually regressed, nevertheless, at the termination of the observation thirty-five to forty-five minutes after the administration of tetraethylammonium chloride, the flow was still higher than the control value. A rise in cutaneous temperature accompanied the increase in blood flow.

In addition to the changes in blood flow, the subjects experienced numbness and tingling, tachycardia, a metallic taste, dryness of the mouth, and variable disturbances of vision with impairment of accommodation.

SUMMARY

The effects of intravenously administered tetraethylammonium chloride on the blood flow in the upper and lower extremities of healthy subjects were studied plethysmographically by the use of the compensating spirometer recorder. In the presence of vasodilatation due to a relatively warm environment of 80 to 85° F, tetraethylammonium chloride produced a substantial increase in blood flow in the upper and lower extremities. The average increase in blood flow was 100 per cent in the forearms and 135 per cent in the legs. In addition to the increase in blood flow, disturbances of vision with impairment of accommodation, metallic taste and dryness of the mouth, and increase in heart rate occurred after injection of tetraethylammonium chloride.

FALSE POSITIVE TESTS FOR SYPHILIS—A FURTHER STUDY OF THEIR INCIDENCE IN SPOROZOITE INDUCED VIVAX MALARIA

JOHN F. KENT* WASHINGTON D. C. WILLIAM B. CLEWELL† & G. ROBERT
COVNEY‡ AND W. CLARK COOPER§
BETHESDA, MD

THE program of testing malarious individuals in prisoner volunteers which was initiated in 1944 by the National Institute of Health has afforded exceptional opportunities to study the sensitive relationship of malaria to false positive tests for syphilis. The use of experimental sporozoite induced infections has made it possible to demonstrate the absence of nonspecific serum reactions in large groups of selected nonsyphilitic individuals before exposure to malaria and to examine successive serum specimens through all stages of the disease. Serums have been sent to the Army Medical Department Research and Graduate School where they have been subjected to standard and experimental tests for syphilis. The first serologic studies which were confined to flocculation tests for syphilis, provided material for an earlier report¹. It was found that the standard flocculation tests in general yielded a high incidence of nonspecific reactions following infection with *Plasmodium vivax* whereas a microflocculation test with cardiolipin antigen² showed relatively few such reactions.

In continuing these serologic studies it has been our purpose to extend the investigation to complement fixation as well as flocculation tests for syphilis and to include certain more recently developed tests that employ cardiolipin antigens.

MATERIALS AND METHODS

Subjects for this study were selected from white male volunteers; only those individuals were considered whose preliminary examinations showed no clinical anamnestic or serologic evidence of syphilis. Successive specimens of serum were obtained from each volunteer before his inoculation with malarin by mosquito bite at two to three day intervals during and immediately following attacks and at weekly intervals during periods of latency. The total time of study in many of the volunteers extended over a period of eighteen months. The serums were preserved in tubes containing dried Verthiolate sufficient to give a final concentration of 1 mg. per milliliter of serum. They were shipped by ordinary mail to the Army Medical Department Research and Graduate School where they were subjected to eight serologic tests for syphilis. Four of these tests employed ordinary tissue extract antigens the remainder were carried out with cardiolipin antigens. The former group included the Kahn standard test the Kline exclusion and Mazzini microflocculation test and the standard Kolmer complement fixation test. The latter group consisted of the Reim-Bussack and VDRL microflocculation tests, a Kolmer complement fixation test³ and a quantitatively standardized complement fixation procedure⁴ which has been designated the F-1-50 test since the end point of 50 per cent hemolysis is employed in its standardization. A total of 6403 serums were examined in this manner. All serologic tests for syphilis were performed.

*The serologic tests which form the basis for this study were performed by Robert W. Sanborn and Harriet M. Boylston whom grateful acknowledgment is made.

§Prison in the Federal Correctional Institution, Scottsbluff, Tex.

RESULTS

The present report is based upon results obtained with 104 individuals who experienced one or more attacks during the course of their malarial infections. Of this group, 78 had been infected with sporozoites of the Chesson strain of *P. vivax*, 17 with sporozoites of the St Elizabeth strain, and 9 with sporozoites of both strains simultaneously. Collectively these subjects experienced 307 attacks of malaria.

The incidence of false positive tests for syphilis was determined from the number of subjects who developed persistent nonspecific reactions after infection with malaria. To be considered as a false positive reactor, it was required that an individual show reactions of plus-minus or greater in at least two successive serums. Of the 104 infected subjects, 75 (72 per cent) developed such false positive reactivity in one or more tests at some time during the course of the disease. This composite group represented 51 (65 per cent) of those infected with the Chesson strain, 15 (88 per cent) of those infected with the St Elizabeth strain, and 9 (100 per cent) of those infected with both strains. The number of individuals included in the last two groups was too small to permit accurate conclusions regarding the relative incidence of false positive reactors. The

frequency with which such reactors were encountered in infections with the St Elizabeth strain appeared high in comparison with the more extensive previous experience¹ in which 61 per cent of 80 similarly infected subjects developed nonspecific reactivity. If this earlier observation is taken as the more trustworthy, false positive reactors would appear to occur with approximately equal frequency in infections with the Chesson or St Elizabeth strains. The exceptionally high percentage of reactors among the few individuals who were infected with both strains may represent a significant difference, but the findings require confirmation in a more extensive series.

Table I illustrates the results obtained in the eight tests for syphilis using successive serums drawn from an individual before, during, and after a primary attack due to the Chesson strain. In this case parasitemia became patent on the

eleventh day after inoculation. On the twenty-second day, nonspecific reactions appeared in all four of the tests that employed ordinary tissue extract antigens. They persisted for intervals varying from five days for the Mazzini test to twenty days for the Kline exclusion test. In marked contrast were the results obtained in the tests employing cardiolipin antigens. The Rein-Bossak and VDRL microflocculation tests as well as the Kolmer and E P 50 complement fixation tests remained negative throughout.

False positive reactions were not ordinarily encountered in advance of the fever or parasitemia of an attack. Occasional exceptions to this rule were observed when relapses occurred before the seropositivity due to preceding attacks had subsided. Reactions appeared, on the average, 8.7 days following the onset of patent parasitemia, the interval varying within the limits of 0 to 39 days depending upon the individual and upon the specificity of the test. These values correspond closely to the mean interval (8.3 days) and range (0 to 30 days) observed in the previous study¹ in which the majority of infections were due to the St. Elizabeth rather than to the Chesson strain. It should be pointed out that while nonspecific reactivity in most individuals was transitory and of low degree, reactions as high as 4 plus were encountered with all the tests. Reactivity due to single attacks of malaria persisted for periods varying from 2 to 77 days, the observed duration again reflecting differences in the individual and in the specificity of the test. False positive reactions of longer duration (23 to 181 days) were observed in twenty-one instances when one or more successive relapses extended the seropositivity due to an earlier stimulating attack.

A comparative analysis of the tests with regard to their specificity for syphilis was based upon the relative number of subjects who became false positive reactors as defined in the foregoing. Separate analyses were made for the three groups that were infected, respectively, with the Chesson, the St. Elizabeth, and the combined strains. These are summarized in Table II which gives the numbers of false positive reactors encountered with each test in successive malarial attacks. As indicated in the previous study,¹ their incidence was highest in primary attacks, the numbers decreasing progressively with succeeding relapses. Among the procedures employing ordinary tissue extract antigens, the Kahn standard test yielded the highest number of nonspecific reactors and the Kolmer complement fixation test the lowest. Of the tests with cardiolipin antigens, the Rein-Bossak and VDRL microflocculation tests showed still fewer reactors and the Kolmer and E P 50 complement fixation tests all but eliminated such reactors. It is noteworthy that the same individual accounted for the only reactions which were observed in the cardiolipin complement fixation tests. These reactions attained the maximal degree of 4 plus during a six day interval. They were paralleled by equally strong reactions in all the tests with ordinary antigens, but no reactivity whatsoever was encountered in the cardiolipin microflocculation tests. All the serologic findings in this case were corroborated by repetition.

Some additional evidence of the relative specificity of the tests could be obtained by comparing them with regard to (a) the interval between onset of pat-

TABLE III. INTERVAL FROM ONSET OF PATENT PARASITEMIA TO APPEARANCE OF FALSE POSITIVE REACTION AND DURATION OF REACTION IN FIFTY SEROLOGIC TESTS FOR SYPHILIS

SEROLOGIC TEST FOR SYPHILIS		KAHN STAND- ARD	KLINE EXCLU- SION	MAZZINI FLOCCU- LATION	KOLMER STANDARD	LEIN ROSSER	VDPR	KOLMER CAR- DIO- LIPIN	E.P. 50 CAR- DIO- LIPIN

	Range	(0-15)	(0-35)	(-20)	(0-39)	(0-22)	(0-6)	(6)	(6)
Duration false positive reaction (days)	Mean	17.4	13.3	8.4	13.6	10.8	5.8		
	Range	(-77)	(2-28)	(1-20)	(3-41)	(3-23)	(3-13)	(6)	(6)

ent parasitemia and the development of the respective false positive reactions and (b) the duration of these reactions. The mean value calculated for each test is given with the range in Table III. It is of interest that the tests in which nonspecific reactions appeared earliest and lasted longest were those which showed the highest incidence of false positive reactions (compare Table II). The occurrence of only one reaction in the complement fixation tests with cardiolipin antigen prevented comparing them with the other tests on this basis but left no doubt as to their superior specificity.

The present findings support the conclusion that in vivax malaria complement fixation tests for syphilis show a higher degree of specificity for syphilis than do the flocculation tests. This superiority was evident regardless of whether results with ordinary tissue extract or with cardiolipin antigens were compared. The introduction of cardiolipin antigens reduced the incidence of false positive reactions in microfloculation tests and virtually eliminated such reactions in complement fixation tests. The specificity of the cardiolipin tests was striking in view of their high sensitivity in syphilis. The observations have obvious implications regarding the serodiagnosis of syphilis particularly where the possibility of a current or recently subsided malarial infection arises.

SUMMARY AND CONCLUSIONS

In continuing studies of malaria as a cause of false positive tests for syphilis 6403 specimens of serum were collected at suitable intervals from 104 nonsyphilitic individuals with sporozoite induced vivax malaria. The serums were subjected to eight serologic tests for syphilis which included flocculation and complement fixation procedures employing either ordinary tissue extract or cardiolipin antigens, 51,224 tests were performed in all.

Seventy-five (72 per cent) of the 104 subjects developed false positive reactivity in one or more of the tests for syphilis at some time during the course of their malarial infections. Nonspecific reactions appeared from 0 to 39 days following the onset of patent parasitemia and lasted from 2 to 181 days. Their time of appearance and duration varied with the individual and with the specificity of the test.

Complement fixation tests for syphilis exhibited a higher degree of specificity for that disease than flocculation tests. Of the procedures employing ordinary tissue extract antigens, the Kahn standard test showed the highest incidence of false positive reactions and the Kolmer test the lowest. Cardiolipin antigens reduced the incidence of nonspecific reactions in microfloculation tests and virtually eliminated such reactions in complement fixation tests.

TRANSIENT POSITIVE WASSERMANN TEST FOR SYPHILIS IN ACUTE HEMOLYTIC ANEMIA

MICHAEL A. RUBINSTEIN M.D.
NEW YORK, N. Y.

COMPREHENSIVE studies of the incidence and nature of the biologic false positive reaction for syphilis with an exhaustive review of literature have been published recently by Davis, Mohr and co-workers, Beerman, Rein and Elsberg, and Kolmer.¹ The reader is referred to these excellent publications for more details.

The case to be reported here is one of acute acquired hemolytic jaundice with spontaneous recovery following transfusions. Transient positive Wassermann tests for syphilis were found during the acute hemolytic attack and became negative after the attack subsided.

Since we have not found any record in the available literature of biologic false serologic reaction in the course of hemolytic anemia, this case seems worthy of reporting.

CASE REPORT

Patient J. Z., a 50-year-old white man, entered the hospital on Sept. 23, 1946, with complaints of yellow discoloration of the skin. The family and the patient's own past history revealed no history of jaundice at any time nor of any exposure to chemicals. The illness had begun a month previously, at which time the patient was told by a physician that he had jaundice and an enlarged liver.

Blood examination on Sept. 19, 1946, showed hemoglobin, 20 per cent; red blood cells, 1,500,000; white blood cells, 9,400; differential count normal; icteric index 24. At that time a slightly enlarged spleen was felt and a moderately enlarged axillary node was noted.

At the time of the patient's admission to the hospital, the skin and sclerae were strikingly yellow. There was an enlarged, firm, movable, slightly tender lymph node in the right axilla, about 5 cm. in diameter. The spleen was felt 1 fingerbreadth below the left costal margin and the liver was felt 2 fingerbreadths below the right costal margin. There was severe anemia (hemoglobin 3.5 Gm., red blood count 1,150,000) with a most pronounced reticulocytosis of 88 per cent and normoblastosis as well as macrocytosis. Serum bilirubin was 4.3 mg. per 100 ml. and the van den Bergh reaction was delayed. The red cell fragility test in saline solutions showed beginning hemolysis at 0.70 per cent NaCl and complete hemolysis at 0.50 per cent NaCl. Sternal bone marrow aspiration revealed a markedly hypercellular marrow with marked increase of erythronormoblastic elements in the differential count (about 60 per cent of the total nucleated cell count of 500,000 in 1 cmm). The urinalysis showed traces of albumin and was negative for bile and sugar.

On the basis of these findings the diagnosis of hemolytic anemia was made.

In order to determine the possible etiologic factor of this hemolytic process, additional studies were made. The Wassermann reaction was reported 4 plus on Sept. 24, 1946, with the Kahn reaction negative. The Donath-Landsteiner test was performed on Oct. 2, 1946, and was negative for the presence of specific cold hemolysins. The lack of history of exposure to cold was also against the Donath-Landsteiner mechanism of hemolysis. Cold agglutinins were absent as well. Agglutination tests for typhoid, paratyphoid A and B, brucellosis, and *Proteus* OX₁₉ were negative. Also, the presence of malarial parasites

From the Medical Division, Montefiore Hospital.

10/25	135	1,430,000													

could not be shown. Blood cultures were negative. Biopsy study of the axillary node revealed granulomatous lymphadenitis with multiple abscess formation; no specific etiology could be suggested, but lymphomatous diseases were ruled out.

Because no underlying disease could be shown or any known exposure incriminated, the hemolytic process was defined as acute acquired hemolytic anemia of unknown origin.

TABLE II SPINAL BONE MARROW STUDIES

Date	9/21/46	10/23/46
Total nucleated cell count (per 1 cmm.)	500,000	150,000
Number of megakaryocytes (per 1 cmm.)	66	2
Differential count (%)		
Myeloblasts	0.5	0.5
Promyelocytes	2.0	1.5
Myelocytes neutrophils	18.0	25.5
Myelocytes eosinophils	0.4	2.5
Non segmented neutrophils	6.0	15.5
Segmented neutrophils	32	12.5
Segmented eosinophils	14	1.5
Segmented basophils	-	0.5
Lymphocytes	1.0	8.0
Hematopoieses	0.5	1.0
Plasma cells	0.5	0.5
Reticulum cells	0.4	-
Proerythroblasts	12	5.5
Erythroblasts	12	5.5
Normoblasts	57.0	25.0

The patient was given repeated transfusions with excellent hematologic and clinical response. There followed a progressive improvement of the patient's general condition; the hepatosplenomegaly gradually receded; the red blood count increased; the reticulocytosis subsided, and the fragility of red cells returned to normal range. On Oct. 1, 1946, the hemoglobin was 13.5 Gm. and the red blood count 3,000,000. On Oct. 14, the Wassermann and Kahn were negative and remained so on all subsequent examinations up to the time of writing.

The patient was discharged in good condition on Oct. 25, 1946, with hemoglobin 13.5 Gm. per 100 cc. and red blood count 4,430,000 per 1 cubic millimeter. The bone marrow examination repeated on Oct. 25, 1946, showed essentially normal findings.

The patient returned to work and since then has been observed in the follow-up hematology clinic. The patient has remained in good health and no clinical or hematologic abnormalities have been noted.

COMMENT AND SUMMARY

A case of hemolytic anemia is reported in which a transient strongly positive Wassermann reaction was found with negative Kahn and Kline tests.

The Wassermann reaction declined gradually with the receding hemolytic process. When the patient was first examined at the height of the hemolytic process (hemoglobin, 3.5 Gm. in 100 cc.; reticulocytes, 88 per cent) the Wassermann reaction was 4 plus; ten days later, with 5.5 Gm. hemoglobin and 58 per cent reticulocytes, the Wassermann reaction was 3 plus; finally, after the following ten days, with 10 Gm. hemoglobin and 60 per cent reticulocytes, the Wassermann reaction was negative throughout.

Although we have not found any other report in the available literature of a biologic false serologic reaction in the course of hemolytic anemia, the case recorded here is not the only one known to us. We have previously observed a

patient with chronic hemolytic anemia associated with Laennec's cirrhosis of liver and complicated by diabetes mellitus in whom positive serologic tests for syphilis gradually became negative after splenectomy. Similar unpublished observations were made by other authors² in cases of acute as well as chronic hemolytic anemia, in which both the Wassermann and the Kahn tests showed transient positive reactions.

It appears therefore that the occurrence of biologic false Wassermann reaction in hemolytic anemia might not be uncommon.

THE PURIFICATION OF DIPHTHERIA AND TETANUS ANTITOXIN BY THE USE OF PEPSIN

ALBERT GLAUBIGER, M.S.
NEW YORK, N. Y.

INTRODUCTION

INVESTIGATIONS by numerous workers have shown that antibodies are closely related to normal serum proteins and occur in the globulin fraction of serum. The chemical and immunologic behavior of antibodies and antitoxins has been reviewed by Kabat¹ in a paper dealing with the immunochemistry of proteins. It has been known for many years that certain antibodies are relatively resistant to destruction by proteolytic enzymes.² This property has been utilized by Paifentiev,³ Pope⁴ more recently by Gerlough⁵ and by others to effect the purification of antitoxins.

Various proteolytic enzymes have been employed to purify antitoxins. Piel⁶ followed at a later date by Mellanby⁷ first studied the action of trypsin and pepsin upon diphtheria antitoxin. It is of interest to note in passing that in 1903 the first commercial patent was granted by the British Patent Office to Oliver Imray¹¹ for the purification of diphtheria antitoxin by the action of trypsin and also by the action of pepsin.

It was many years following the investigations of Piel and Mellanby that interest was again revived by Paifentiev in the use of enzymes to purify antitoxins. The studies of Paifentiev³ were followed by the investigations of Pope⁴ who reported that in addition to the use of pepsin satisfactory results could also be obtained with trypsin, papain, maltin (obtained from a commercial preparation of diastase), and fibinolysin. Modern and Ruff¹² confirmed the observations of Pope concerning the peptic purification of diphtheria antitoxin. The enzymatic purification of tetanus antitoxin was confirmed by Sandoz and Richon¹³ and also by Modern and Ruff¹⁴.

Cothill and co-workers¹⁵ have developed a process to purify antitoxins using the enzyme Taka diastase. More recently Northrop¹⁶ has prepared purified diphtheria antitoxin by means of digestion of the toxin-antitoxin complex with crystalline trypsin followed by fractional precipitation with ammonium sulfate.

This discussion would be incomplete without a brief statement concerning the effect of proteolytic enzymes upon antibacterial sera. Antibacterial antibodies behave somewhat differently toward peptic action than do antitoxic antibodies. Schultze¹⁷ has observed that diphtheria, tetanus and pertussis antitoxic sera are less extensively hydrolyzed than normal horse serum. On the other hand, antibacterial sera prepared against pneumococcus and streptococcus are hydrolyzed at the same rate as normal horse serum. Grabar¹⁸ noted

From the William Hallock Park Laboratory, Bureau of Laboratories, Department of Health.

Received for publication Feb. 1, 1948.

that type I antipneumococcus horse serum which was subjected to peptic action lost one-half of its antibody nitrogen with an accompanying loss of only one-fourth of the total nitrogen. The observations of Schultze and Giarab have been confirmed by van der Scheer and associates¹⁹ in their electrophoretic examination of digested sera.

The pursuit of suitable methods for treating immune horse serum in order to avoid serum reactions in human beings has spurred the development of the enzymatic process for the purification of antitoxins. Weil, Parfentiev, and Bowman²⁰ were the first to study the antigenic qualities of horse serum antitoxin. They found that treating the antitoxic serum with pepsin impaired the antigenicity of the serum to a great extent.

The investigations of Parfentiev and associates were followed by the studies of Coghill and co-workers¹⁵ on the use of the enzyme Taka diastase to eliminate horse serum specificity from antitoxins. The premise underlying the use of Taka-diastase is that the carbohydrate portion, which is associated with the pseudoglobulin fraction of horse serum is responsible for serum reactions in human beings. Rimington²¹ was the first to isolate and study the chemical properties of this polysaccharide. However Coghill and Creighton, using the chemical procedures of Rimington, demonstrated the nonspecific nature of the carbohydrate associated with horse serum pseudoglobulin.

Kass, Scheerago, and Weaver²² have investigated the effects of enzymic digestion upon the antigenic qualities of antitoxic and normal horse plasmas. Their plasmas were digested with *Aspergillus oryzae* diastase, malt diastase and pepsin. Using the Schultz-Dale technique in their anaphylactic studies on guinea pigs, they found that the digested antitoxins were antigenically related no matter which of the three enzymes mentioned was utilized for digestion of the horse plasmas.

There are available two general methods of purifying antitoxic sera by means of pepsin. These methods are outlined by Parfentiev and Pope, respectively. In the method of Parfentiev the unwanted proteins of antitoxic serum are digested at about pH 4.0*. This is followed by the adsorption of nonantitoxic proteins present in the digest product†. In his process Parfentiev permits the digestion of an antitoxic serum to continue to a point where proteoses and other substances commonly associated with the enzymatic decomposition of proteins are produced. These substances as well as some pepsin which may remain must be adsorbed from the solution since they are not readily separated from the antitoxic proteins by the usual method, that is fractional precipitation with ammonium sulfate. In practice, various adsorbing agents are employed such as aluminum cream,²⁴ tricalcium phosphate,²⁵ or other similar substances. In a subsequent patent which Parfentiev obtained,‡ digestion of an antitoxic serum is carried out at pH 3.0 to pH 3.2 at 37° C. for several hours. This is again followed by adsorption with tricalcium phosphate in a manner similar to the procedure, previously described.

*As outlined in U. S. Patent No. 2,065,196 (1936).

†As outlined in U. S. Patent No. 2,123,198 (1938).

‡Namely U. S. Patent No. 2,175,090 (1939).

In the procedure of Pope antitoxic serum is treated with pepsin for a short period of time at room temperature. This step is followed by rapid heating of the serum in the presence of a large quantity of a salt to some critical temperature at which temperature the unwanted proteins are coagulated. The antitoxic proteins remain in solution and may readily be separated from the coagulum by filtration or centrifugation. This is followed by the addition of more salt with the subsequent precipitation of the antitoxic proteins. This method is based on the following considerations. According to Pope diphtheria antitoxin is a complex molecular aggregate which consists of two parts. One part is readily denatured by heat, strong acids or alkalis and so on, while the other part which carries the antitoxic properties is not readily denatured. This theory has been substantiated for diphtheria antitoxic horse pseudoglobulin by Petermann and Pappenheimer⁶ as well as for bovine pseudoglobulin.

It becomes evident at once from an examination of the two methods that basic differences exist between the procedure of Puissant⁵ and that outlined by Pope. The former method depends upon the digestion of serum proteins with the concomitant production of substances usually associated with the enzymatic decomposition of proteins. The method of Pope consists in a disaggregation of the pseudoglobulin by partial enzyme action followed by heat, which results in the separation of antitoxic from nonantitoxic protein. In the latter instance, therefore, true digestion does not take place to any considerable extent.

PROCEDURES

The principal enzyme used for the preparation and purification of antitoxins on a commercial scale is pepsin. The use of pepsin has obviated the difficulty experienced in controlling the digestion process as well as the difficulty in separating the enzyme itself from the solution of antitoxin once its function in the purification process has been completed. By varying the pH value of the solution it is a simple matter to control digestion and to obtain a solution of antitoxin entirely free of peptic action. Moreover commercial preparations of pepsin of various digestive potencies and of reasonable purity may be purchased in sufficient quantities. For the foregoing reasons pepsin is employed in the following procedure to effect the purification of diphtheria and tetanus antitoxin.

Processing of Plasma and Globulin—The entire process given below was carried out in a jacketed vat having a capacity of 65 liters. Sample batches of antitoxic horse plasma or antitoxic pseudoglobulins were treated with pepsin.

- 1 Antitoxic plasma or antitoxic pseudoglobulin recovered from ammonium sulfate fractionation of immune horse plasma is diluted with a sufficient volume of physiologic salt solution to reduce the total solid content to 2 to 3 per cent.

- 2 Four tenths per cent phenol is added to the diluted plasma or globulin solution. The addition of phenol serves not only as a preservative but also aids in the heat denaturation process listed below.

- 3 The solution is then adjusted to pH 3.1 with solid citric acid. This procedure is carried out with constant stirring by means of a mechanical stirrer.

4 A small quantity of powdered pepsin 1:10,000 is added and the solution is stirred until all of the pepsin is dissolved. The pH value of the solution rises to 3.2. The quantity of pepsin chosen is such that the value of the ratio of the amount of pepsin to the quantity of protein (pepsin/total solids) is less than 1:10.

5 The solution pH 3.2 is kept for one hour at room temperature 20 to 25° C.

6 After one hour has elapsed, the pH value of the solution has risen to 3.23 to 3.26. A maximum rise of 0.06 pH is permissible in this procedure otherwise extensive digestion of horse serum proteins takes place with the production of substances commonly associated with the enzymatic decomposition of protein. The solution is adjusted to pH 4.2 with rapid stirring, using 30 per cent sodium hydroxide solution. A white precipitate becomes evident. The precipitate is a complex aggregate of denatured protein which was associated with the antitoxic pseudoglobulin fraction of the plasma⁷ combined with pepsin.

7 After one hour has elapsed, 14 per cent by weight of ammonium sulfate is added and the solution is heated as rapidly as possible by means of steam to 58° C in order to coagulate the unwanted proteins. The solution is kept at 58° C for one hour. It is then permitted to cool.

8 After the precipitate has been allowed to settle for about forty eight hours, the supernatant solution is siphoned off and filtered through a Büchner filter funnel covered with a layer of Super-cel. After filtering all of the supernatant solution, the coagulum is then passed through the same filter. Both the supernatant solution and the coagulum are filtered by gravity.

9 The filtrate with a pH of about 4.1 is adjusted to pH 7.0 with 30 per cent sodium hydroxide solution which is added with constant stirring. Twenty per cent by weight of ammonium sulfate is then added to the solution and the antitoxic globulins are precipitated. The solution is then permitted to stand for one-half hour and is filtered through hardened filter paper.

10 The precipitate is pressed dry and placed in a cellophane bag. The precipitate is dialyzed until the sulfate ion is negligible. After dialysis is complete, the pH of the solution is about 6.3. The solution of antitoxin is brought to the neutral point by the addition of normal sodium hydroxide solution. One per cent by weight of sodium chloride is added to the antitoxin as well as 0.05 per cent Merthiolate and 0.35 per cent phenol. The potency of the antitoxin solution is then tested by flocculation or by animal protection tests.

Chemically pure reagents were used throughout the procedure. Various commercial brands of pepsin were employed of digestive potencies ranging from 1:3,000 to 1:10,000. Hydrogen-ion values of the antitoxin solutions were determined with an Electron-ray pH meter in conjunction with a MacInnes-Bellier condenser type of glass electrode. This apparatus has been adequately described in a previous paper.²⁸

Sensitivity Tests—Sensitivity tests were performed on rabbits previously immunized to determine whether there were any horse serum reactive protein

in the antitoxin solutions under test. The sensitizing fluid consisted of an alum precipitated normal horse serum prepared by adding an equal volume of a 4.0 per cent solution of aluminum potassium sulfate to sterile normal horse serum. The precipitate is allowed to settle for twenty-four hours. The supernatant solution which contains but a trace of protein is discarded and replaced with a volume of physiologic salt solution equal to the original volume of normal horse serum.

Rabbits were immunized before being used for sensitivity tests by intraperitoneal injections with 5 ml. doses of alum precipitated normal horse serum once a week for five consecutive weeks. It was observed that the intradermal injection of normal horse serum containing as little as 0.02 mg. of protein antigen produced a skin reaction in a sensitized rabbit. The shaved back of a white rabbit was marked off into squares of approximately 9 sq. cm. with a blue marking pencil. One-tenth milliliter of the test fluid was injected intradermally into each of the squares. The test fluids consisted of horse plasma, antitoxic globulins recovered by fractionation of plasma with ammonium sulfate, and antitoxic pseudoglobulins obtained by means of the enzyme process previously described. All of the test fluids were diluted with 5 volumes of physiologic salt solution before injection into a rabbit. In practice it was found necessary to dilute the plasmas and antitoxic globulins not treated by the enzyme process with at least 5 volumes of saline solution in order to contain the skin reactions within the limits of the squares marked off on the back of the rabbit. Skin reactions were observed for a period of seventy-two hours; then the rabbits were discarded. The rabbits thus discarded were not employed in any subsequent test.

RESULTS

The results of the purification of diphtheria antitoxin by the use of pepsin are shown in Table I. The second column gives the material which was treated by the enzyme process. The next column gives the pH value at which the enzyme treatment was carried out. This is followed by the potency of the pepsin which was added to the diluted antitoxin solution. The next column gives the potency of the antitoxin before and after enzyme treatment and concentration in units per milliliter obtained by the Ramon flocculation test. The remaining columns of the table are devoted to data on skin sensitivity tests before and after pepsin purification. The rabbit skin reactions are denoted as follows: 1 plus erythema, 2 plus erythema and edema, 3 plus erythema, edema, and necrosis, $\frac{1}{2}$ plus a mild reaction. No visible skin reaction is recorded as zero.

Table I indicates that the first four lots of enzyme purified antitoxin produced slight skin reactions, especially the first lot which was treated at pH 4.0 with 1:3,000 pepsin. Moreover, there was a twofold increase in the antitoxic titer as shown by flocculation tests. Beginning with the fifth lot, the potency increased about three and one-half times that of the untreated antitoxin. Treating the diluted antitoxin with 1:10,000 pepsin at pH 3.2 for one hour at room temperature, according to the method described previously, resulted in an antitoxic globulin which gave no skin reaction. An increase in the pH value at which

enzyme purification was carried out resulted in an antitoxin which produced an increased skin reaction. From an examination of Table I it is evident that the untreated antitoxic globulins in all cases gave more severe reactions than the enzyme purified globulins. Table I also shows that purification at pH 3.2 with 1 10,000 pepsin gave a more potent product than purification and concentration at the same pH value with 1 3,000 pepsin. Finally, while the untreated

antitoxin gave skin reactions which became intensified as time increased, the intensity of the skin reactions resulting from some of the pepsin-treated antitoxins diminished.

Table II shows the results of enzyme purification of tetanus antitoxin. The data are arranged in the same manner as in Table I. The potency of the antitoxins is expressed in units per milliliter as obtained by animal protection tests. An examination of Table II shows that approximately the same results were obtained as with diphtheria antitoxic globulins. It is to be noted that tetanus plasma gave the most severe skin reaction. Fractionation of plasma with ammonium sulfate reduced the intensity of the skin reaction somewhat. However the enzyme-treated globulins almost invariably gave no visible skin reaction. The results obtained with the last three lots shown in Table II indicate that antitoxic sera may be purified by treatment with pepsin in accordance with the procedure outlined in this paper, regardless of whether the initial material is immune horse plasma or antitoxic pseudoglobulins recovered from ammonium sulfate fractionation.

Table III contains the results of heating diluted tetanus antitoxic plasma and diluted normal horse serum to 58° C. at pH 4.2 in the absence of salt and

stood for one hour a copious precipitate was evident The diluted plasma was then divided into three aliquot portions The first was centrifuged and the precipitate was separated from the remainder of the solution The precipitate was then suspended in physiologic saline solution and adjusted to pH 6.95 The second portion of diluted plasma was heated to 58° C for one hour and placed in the refrigerator overnight The next day the precipitate was removed by filtration and the filtrate adjusted from pH 4.17 to pH 6.96 This procedure

was repeated with the third portion of diluted plasma with the exception that before heating the solution to 58°C , 5 per cent by weight of dry sodium chloride was added. These procedures were also carried out using normal horse serum which had been treated with 1:10,000 pepsin in the manner outlined in this paper. The protein nitrogen content of the solutions was determined by the micro-Kjeldahl procedure of Parnas and Wagner.²⁹ Skin tests were made with solutions of equal nitrogen value. One-tenth milliliter of the test fluids contained 0.2 mg of protein nitrogen.

An examination of the data in Table III shows that both the diluted normal horse serum and the diluted tetanus plasma having a protein nitrogen content of 2.0 mg per milliliter gave the most severe reactions. This fact has already been mentioned in connection with the skin test data shown in Table II. Less severe reactions were observed with diluted normal horse serum and with the diluted tetanus plasma which had been heated to 58°C in the absence of salt. From an examination of the fourth column of Table III it is evident that there was no visible reaction resulting from the intradermal injection of the diluted tetanus plasma or the diluted normal horse serum which had been heated to 58°C in the presence of 5 per cent sodium chloride. The unheated pepsin-protein precipitates recovered from the diluted tetanus plasma and the diluted normal horse serum at pH 4.20 gave no visible skin reactions.

Further studies indicated that all but a trace of heat coagulable (100°C) proteins were absent from the solutions of normal horse serum and tetanus plasma which had been heated to 58°C at pH 4.20 in the presence of 5 per cent sodium chloride. Moreover 3.3 per cent of heat coagulable protein still remained in the solution of tetanus plasma which had been heated to 58°C in the absence of salt. Also 2.2 per cent of heat coagulable protein was still present in the diluted normal horse serum which had been heated to 58°C in the absence of 5 per cent sodium chloride. These results indicate that the skin reacting substances which are present in tetanus plasma and in diluted normal horse serum vary with the amount of heat coagulable protein which remains in the solution after the enzyme process is completed.

The lack of any visible skin reaction from the injection of the pepsin protein precipitate which occurs at pH 4.2 indicates that this precipitate consists of a complex aggregate of denatured protein which has become incapable of eliciting any response from a sensitized rabbit. Furthermore this denatured protein is associated with pepsin which has been added to the diluted plasma or serum. Tests show that the added pepsin is absent from the diluted plasma or serum at pH 4.2 after heating to 58°C in the presence of 5 per cent sodium chloride or 14 per cent ammonium sulfate. By the use of a modification of the hemoglobin test devised by Anson³⁰ the preceding solutions as well as the enzyme-treated globulins mentioned in Tables I and II were found to be free of any peptic action after the enzyme procedure was completed.

DISCUSSION

The procedure described in this paper for the purification of antitoxic horse plasma and antitoxic pseudoglobulins has been tried using other types of normal

and immune animal sera. I have observed that if bovine or goat globulins are treated with pepsin and the diluted globulin solution is adjusted to pH 4.2 a copious white precipitate appears in a short time. This observation has been made with normal horse serum as shown in Table III. Other investigators²¹ besides Pope have made similar observations.

It has been known for some time that crystalline proteins such as edestin²² are capable of removing all hint traces of pepsin from a solution at pH 4.0. Waldschmidt-Leitz and Kofran²³ have observed a similar phenomenon with melon seed globulin. Northrop²⁴ has demonstrated that the pepsin-edeitin precipitate may be dissociated under suitable conditions so that the original activity of the pepsin is restored. Nemeth and colleagues²⁵ have discussed the role of enzymes in protein denaturation. The precipitate at pH 4.2 consists of serum proteins which have been denatured by proteolytic enzymes. In the case of horse serum proteins which have been denatured with pepsin at pH 4.2, such proteins are incapable of causing a skin reaction in rabbits sensitive to horse serum as shown by the data in the fifth column of Table III.

This discussion would be incomplete without a brief statement concerning the clinical use of enzyme purified antitoxins. Out of twenty-six recorded cases of patients treated with enzyme purified tetanus antitoxin, twenty patients recovered completely, with only one developing serum sickness and one having a mild reaction to the antitoxin. The first patient had mild serum sickness which occurred about eight days following the first injection. It was learned subsequently that the patient was horse serum sensitive and had been given the first dose of tetanus antitoxin obtained by ammonium sulfate fractionation. The other patient received a total of 3,580,000 units of antitoxin in a period of nine days. This patient also recovered despite a mild reaction to the antitoxin. All the familiar routes of injection were employed in all the patients. Seven of the patients had clinical histories of bronchial asthma and horse serum allergy. The age of the patients treated with the antitoxin ranged from four to sixty-five years.

In another series of clinical tests, prophylactic injections of enzyme purified tetanus antitoxin were given to fifty patients in an accident ward of a hospital. All of the patients had clinical histories of asthma, hay fever or horse serum sensitivity. No immediate or delayed reactions were observed.

Enzyme purified diphtheria antitoxin has been used in two patients with diphtheria who were known to be sensitive to horse serum. One of the patients was a child of four, the other was an adult about sixty years old. Both patients recovered. Neither of the patients exhibited any signs of serum sickness.

Both the enzyme purified tetanus and diphtheria antitoxins have been employed on other asthmatic or horse serum sensitive patients with excellent results.

SUMMARY

A method has been described for the purification of diphtheria and tetanus antitoxin by the use of pepsin. The results of the purification of antitoxic horse

plasma or antitoxic globulins by pepsin indicate that the enzyme treated globulins give no skin reaction in rabbits which have been immunized to the proteins of normal horse serum. Some clinical results of the use of enzyme purified antitoxins are also described.

The author takes this opportunity to thank Mr C K Greenwald, Mr A. Mackey, and Mr M. Burgei for their assistance in performing the sensitivity tests and for the determination of the potencies of the samples of tetanus antitoxin, and also Mrs E Crozman for obtaining the potencies of the samples of diphtheria antitoxin by the Ramon flocculation test.

ANTIRETICULAR CYTOTOXIC SERUM IN THE TREATMENT OF ARTHRITIS

OBSERVATIONS ON FORTY-FOUR CASES

WALTER M. SOLOMON, M.D., AND ROBERT M. STECHER, M.D.
CLEVELAND, OHIO

ANTIRETICULAR cytotoxic serum (A.C.S.) has been described as an effective remedy in different chronic conditions including several types of rheumatism. The present study was planned to test its effectiveness in the treatment of two types of chronic joint disease—rheumatoid arthritis and degenerative joint disease.

Boidet originally observed that antibodies were formed in animals under proper conditions after injection of human material such as leucocytes, liver or kidney cells. The serum of such immunized animals produced varying reactions when injected into human beings. Large doses caused toxic effects while small doses sometimes produced beneficial stimulating effects.

Bogomolets¹ became interested in this phenomenon in 1929. After considerable study he concluded that connective tissue was the most important element in antibody production. He therefore attempted to develop antigens by injecting material from the human reticulo-endothelial system. His report in 1943 that his serum was effective in the treatment of rheumatism stimulated interest in America and since that time several reports have appeared. The theoretic considerations have been reviewed by Straus².

The material³ used in this study was the same as that supplied for other studies (Rogoff and co-workers³). Two types of material were provided. One contained antireticular cytotoxic serum in rabbit serum and the other contained only untreated rabbit serum. The identity of these sera was unknown to us until the study was completed. The antireticular cytotoxic serum was prepared by injecting into rabbits and goats a saline extract of spleen and bone marrow secured within ten hours of death from persons under 40 years of age, apparently in good health, who died from sudden injury. The saline extract was injected intravenously into rabbits or goats. The immunized animals were bled and the sera were dehydrated and stored until needed. When used it was diluted to a 10 per cent solution in normal saline.

Bogomolets's method of administration was followed closely. Injections of the antireticular cytotoxic serum and the control serum were given subcutaneously. The first dose was 0.5 c.c. followed at intervals of three to five days with a second dose of 1.0 c.c. and a third dose of 1.5 cubic centimeters. Three doses constituted a series. A second and third series were given at six week intervals. The three series were considered a complete treatment.

From the Department of Medicine of Western Reserve University Medical School at City Hospital.

Received for publication Mar. 1, 1948.

³Prepared by H. Goldblatt at the Institute of Pathology, Western Reserve University Medical School.

The patients were selected from the Out Patient Department of Cleveland City Hospital. All were ambulatory and many had been under observation for months to years. The diagnoses of rheumatoid arthritis and of degenerative joint disease depended upon the usual clinical criteria and were supported by laboratory and radiologic evidence. Patients in each category were selected alternately for the antireticular cytotoxic serum and the control serum.

RESULTS

Table I shows the results in rheumatoid arthritis. Of the twenty patients with rheumatoid arthritis, seven were subjected to three complete series of injections with antireticular cytotoxic serum and seven had three complete series of injections with control serum. In addition to these fourteen patients there were eight patients who received less than the three complete series, five had

TABLE I RHEUMATOID ARTHRITIS

antireticular cytotoxic serum and one the control serum. Table II shows twenty four patients with degenerative joint disease six received three complete series of injections with antireticular cytotoxic serum and ten received three complete series with control serum. As with the patients with rheumatoid arthritis there

TABLE II DEGENERATIVE JOINT DISEASE

	NUMBER	AVERAGE AGE (YR.)	AVERAGE DURATION (YR.)	OBJECTIVE RESULTS			SUBJECTIVE RESULTS		
				BETTER	SAME	WORSE	BETTER	SAME	WORSE
A. C. S.									
Completed series	6	56	9	0	6	0	4	2	0
Total cases	14	58	10	1	13	0	6	8	0
Total (%)				7	93		43	57

Total (%)				20	80		50	50	

were eight additional patients who received one or two series of antireticular cytotoxic serum but did not finish the three complete series.

Reactions were more frequent after injections with antireticular cytotoxic serum than with control sera. A general reaction including mild fever, malaise

and nausea was observed four times after antirreticular cytotoxic serum and once after control serum. Local reactions with tenderness, swelling, and redness at the site of injection occurred after eighteen injections with antirreticular cytotoxic serum and four times after injections of control sera.

The tables list both objective and subjective results. Objective improvement meant a decrease in swelling, increase of motion, or loss of tenderness. The subjective results were based upon the patients' own estimation of their conditions. The subjective results followed very closely the objective results in most instances. In the patients with rheumatoid arthritis receiving antirreticular cytotoxic serum two were better, eight were unchanged, and two were worse objectively, compared with one better, seven unchanged, and three worse subjectively. Of the fourteen patients with rheumatoid arthritis, seven of whom received three complete series of antirreticular cytotoxic serum and seven of whom received three complete series of control serum, the tabulations of objective and subjective results were identical.

Subjective improvement was more apparent than objective improvement in the patients with degenerative joint disease. Of fourteen patients receiving antirreticular cytotoxic serum, only one was listed as having objective improvement while six thought they had been benefited. It seemed significant that of the ten patients receiving control serum, two were listed as having objective improvement and five thought they had been helped.

No significant difference was observed between the use of antirreticular cytotoxic serum and control serum. Every patient was seen over a period of at least six months and many were under observation for over a year. Any critical observer at all familiar with the clinical vagaries of rheumatoid arthritis and of degenerative joint disease recognizes the frequency with which patients with these chronic diseases describe variations in the degrees of their symptoms, especially when they are observed for a long period of time and under changing therapeutic regimens. Such mild variations, occurring as they often do spontaneously, are of no significance in judging therapeutic effectiveness unless they are sustained. The authors feel that the variation in patients' symptoms recorded in this study are not an indication of specific therapeutic effect for antirreticular cytotoxic serum.

The results obtained in this study are in essential agreement with other recent reports. Bach⁴ treated forty-eight patients, thirty-five had rheumatoid arthritis and the others had rheumatic fever, ankylosing spondylitis, gonorrheal arthritis, osteoarthritis, and nonarticular rheumatism. Bach noted clinical improvement in fourteen, in seven it was definite and in seven only slight. The patients with definite improvement included three with rheumatoid arthritis, one with rheumatic fever, one with gonorrheal arthritis, one with ankylosing spondylitis, and one with muscular rheumatism. In two of the three cases of rheumatoid arthritis the benefit observed might well have been due to bed rest for over a month in a hospital. Two months after discharge both patients suffered a relapse. The author discusses the difficulty in evaluating the influence of the serum in producing the benefits observed.

Rogoff and associates² treated twenty nine patients with rheumatoid arthritis and ankylosing spondylitis with antireticular cytotoxic serum and fourteen patients with rabbit serum. They noted that 10 per cent of the patients had symptomatic improvement, 10 per cent had objective improvement, 55 per cent were unchanged and 24 per cent were worse. Results of the same order were observed with the use of control rabbit serum. They concluded that antireticular cytotoxic serum therapy produced no dependable benefit in patients with rheumatoid arthritis.

COMMENT

The effects observed from the treatment of twenty patients with rheumatoid arthritis and of twenty four patients with degenerative joint disease were so slight and inconclusive that further investigation did not seem to be justified. Despite the small number of patients treated and the negative results obtained this report is in complete agreement with recent similar observations on this subject and is presented to place these results on record as part of the observed experience with this form of treatment.

THE THIOCYANATE CONTENT OF SALIVA IN NORMAL AND HYPERTENSIVE SUBJECTS BEFORE AND AFTER INGESTION OF THE DRUG

E J FISCHMANN, M D, AND ANDOR FISCHMAN
AUCKLAND, NEW ZEALAND

EARLY studies, as surveyed by Luckint,¹ are inconsistent regarding the thiocyanate content of human saliva in health. More recently Reissner² found a normal range of 2.4 to 20.0 mg per 100 ml with an average of 10.0 mg per cent thiocyanate (SCN). Claims regarding salivary SCN changes in certain pathologic conditions³ remained unconfirmed. Similar difficulties have been encountered with other salivary constituents. With special reference to calcium and phosphorus, Beeks and Wainwright⁴ criticized older reports because the method of obtaining specimens was not stated, or was unsatisfactory, and because of disregard for the rate of flow. They suggest that the collection of resting saliva gives uniform and comparable results. Such criticism also applies to most reported thiocyanate studies.

In 1925 Nichols⁵ found that SCN concentration of saliva is considerably raised after SCN administration. Tastaldi,⁶ in hypertensive patients treated with potassium thiocyanate (KSCN), found that the saliva:serum ratio decreased with increasing serum levels. He did not report on natural salivary SCN. The SCN content of other body fluids was repeatedly studied in thiocyanate treated hypertensive patients and as a means of measuring extracellular fluid volume.

The aim of the present study was to obtain more reliable and uniform information than has hitherto been available regarding natural and post-ingestion salivary thiocyanate levels by using a standardized method of collection, and by relating values to the rate of flow.

MATERIAL AND METHOD

Three groups of salivary SCN determinations were made: (1) Determination of the natural level in each of thirty-five healthy subjects. (2) Three determinations of the pre-ingestion level at short intervals in thirty-five patients with raised blood pressure. (3) Determination of the level at intervals of one to two weeks, for periods varying from four weeks to several months, in thirty patients with raised blood pressure during treatment with thiocyanate salts. The drug was administered as described in a previous paper. In the second and third group the serum level also was determined. One hundred and forty determinations were made before and one hundred and seventy-six after administration of KSCN.

The subject was instructed to have nothing to eat or drink on the morning of the test, not to brush his teeth, and not to smoke. The specimen was collected between 9 and 10 A.M. the subject bent his head over a funnel placed on a graduated centrifuge tube and the saliva was allowed to flow freely with exclusion of movements of the jaw, spitting, and so forth. The time of collection was ten to thirty minutes. The specimen was then centrifuged and 1 cc of the clear supernatant fluid were used for the determination of thiocyanate by the method of Schreiber⁷ as modified by Crundall and Anderson.⁸

Naturally Occurring Salivary Thiocyanate —

Concentration of SCN in Milligrams Per Cent The arithmetic mean in thirty five normal subjects was 13.4 ± 1.1 mg per cent. The lowest and highest observed values were 3.1 and 27.5 mg per cent. No significant difference was demonstrable between different age groups and the sexes.

The arithmetic mean for nonsmokers was 11.7 ± 1.0 mg per cent. The range varied from 3.1 to 26.5 mg per cent. The arithmetic mean for smokers was 17.5 ± 2.1 mg per cent. The range varied from 8.1 to 27.5 mg per cent. The means differed considerably, the ranges however overlapped to such an extent that no significantly different range for nonsmokers and smokers could be established. Patients were arbitrarily divided into three groups according to the rate of flow (under 10, 10 to 20 and above 20 cc per hour respectively).

TABLE I RELATION OF SCN CONTENT OF SALIVA OF HEALTHY AND HYPERTENSIVE SUBJECTS TO THE RATE OF FLOW AND SMOKING

GROUP	MG PER CENT						MG PER HOUR

RF over 15 cc/hr	15.2	1.1	6.0	3.3	2.5	1.9	1.93	3.66	1.76	1.63	0.72	0.94

RF Rate of flow. N normal group. H hypertensive group. σ standard deviation of the mean. σM standard error of the mean.

Comparisons of the arithmetic means of the corresponding milligram per cent values (22.5, 14.3, and 9.8) suggest an inverse relationship between rate of flow and SCN milligram per cent concentration. The correlation coefficient, $r = -0.65 \pm 0.10$, is significant. In order to show that the high values encountered in the low rate of flow group were not due to smoking, nonsmokers and smokers were grouped separately into two groups of higher and lower rate of flow (below and above 15 cc per hour). Table I shows that the inverse relationship of rate of flow and concentration was present irrespective of smoking. There was practically no overlapping of concentrations of nonsmokers in the low and medium rate of flow groups, the highest concentration in the latter being 15.5 mg per cent, the lowest in the former being 15.1 mg per cent.

The arithmetic mean in thirty five hypertensive patients was 14.7 ± 1.0 mg per cent. The lowest and highest observed values were 4.7 and 31.1 mg per cent. This range practically coincides with the one found in normal subjects and the arithmetic means do not differ significantly. Figures in Table I also demonstrate

the inverse relationship between rate of flow and milligrams per cent concentration of SCN in hypertensive patients

SCN Content of Saliva Expressed as Milligrams Per Hour Normal values in nonsmokers and smokers and in hypertensive individuals are shown in Table I. It appears that there is a direct relationship between rate of flow and milligram per hour values

Concentration of SCN After Ingestion of KSCN—Natural SCN value means the SCN content of saliva without ingestion of SCN salts. Additional value expresses the amount of ingested SCN diffusing into the saliva. Total value is the actual value observed after ingestion and is made up of the sum of the natural and additional values. The range of concentration of SCN after ingestion of varying doses of KSCN was 16.8 to 36.9 mg per cent. The range of additional values after ingestion fell between 2.0 and 21.7 mg per cent. In general a rise or fall followed an increase or decrease in the dose, the concentration remaining constant on a given dose. Often however after a marked initial rise further increase was only slight on raising the dose. In one subject the additional value of 17 mg per cent rose to only 19.6 on raising the dose from the

TABLE II. MEAN AND RANGE MILLIGRAM PER CENT CONCENTRATIONS ADDED TO NATURAL MILLIGRAM PER CENT CONCENTRATIONS OF SALIVA AFTER INGESTION OF KSCN, AT VARYING SERUM LEVELS

initial 0.4 to 2 grams. In another subject the additional value of 15.2 mg per cent with a dose of 0.6 Gm rose to 17.1 with 1.2 grams. The average concentration accompanying doses ranging from 0.13 to 1.2 Gm rose from 25.2 to 31.2 mg per cent. Ranges overlapped widely and were indistinguishable for different doses. The additional value was higher in the low than in the two upper natural value groups, with only slight difference between the latter two (Table II). There was a slight rise in total average saliva concentration, accompanying increased serum values. The rise was less pronounced than in serum. Ranges accompanying divergent serum levels overlapped. The relation of serum levels and additional values was similar (Table II). In most cases the additional concentration in saliva was two to three times higher than that in the serum, the saliva:serum ratio ranging from 7 to 12. Only in one case out of thirty was the ratio definitely lower than 1. The range of milligrams per hour values after ingestion was 1.26 to 10.10, the range of additional concentration, 0.43 to 6.05. There was much greater irregularity in variation of milligrams per hour than in milligram per cent values, owing to fluctuation of the rate of flow.

DISCUSSION

The normal range of milligram per cent concentrations found in the present series is wider than that in most previous publications the average being somewhat higher. This is chiefly due to the different method of collection.

Becks and Wainwright⁴ pointed out that most constituents of human saliva show increased concentration with a higher rate of flow. This applies both to milligram per cent and milligram per hour values. Two exceptions were found in human resting saliva, the calcium and phosphorus concentrations expressed in milligrams per cent are inversely proportional to the rate of flow while milligram per hour values show an increase with a higher rate of flow. According to the present study, SCN shows this same type of exceptional behavior.

Past attempts to establish a normal salivary SCN range and to relate abnormal values to certain pathologic states¹ were prevented by wide overlapping of ranges.¹⁰ It seems that unless the normal range can be narrowed with reference to certain factors such as rate of flow or smoking SCN determinations will be of no diagnostic value. Lickert¹ attempted to reduce the range by classification according to smoking. The present findings suggest that this alone is not enough. By employing a standard method of collection and by grouping results according to rate of flow and smoking the range has been narrowed down. Future research must decide whether this will be sufficient to define abnormal values.

Caviness, Bell, and Satterfield¹¹ found an inverse relationship between the height of blood pressure and naturally occurring serum thiocyanate. They considered thiocyanate a true natural depressor substance. This was denied by others.¹²⁻¹³ Findings in saliva also show no difference in SCN concentrations between normal and hypertensive patients.

Lack of constant correlation between dosage and salivary SCN also between serum and salivary SCN levels renders salivary SCN determinations unsuitable for the control of SCN therapy in hypertension. The tendency to inverse relationship between natural and additional concentration has a levelling effect on the total concentration observed obscuring changes due to change in dosage.

The higher the salivary SCN level at the time of administration of a given amount (regardless of whether this level is the patient's natural level or whether it was produced by previous administration of the drug) the smaller a proportion of the added amount will diffuse into the saliva. Since the height of dosage is limited by toxic effects, it could not be ascertained whether the salivary SCN can be raised to a point where further administration of the drug will not produce a further rise in salivary SCN. These observations together with the discrepancy found between saliva and serum concentrations seem to give experimental support in human beings to the suggestion put forward by Elkinton and Taftel,¹⁴ based on animal experiments that the applicability of SCN distribution as a measure of extracellular body fluid volume is limited because of uneven distribution of SCN possibly owing to formation of depots. Saliva seems to constitute such a depot.

SUMMARY

The thiocyanate content of human saliva has been determined using a standard method of collection and considering the rate of flow. Results are expressed in milligrams per cent and in milligrams per hour.

SCN differs from most salivary constituents in that milligram per cent values are inversely related to the rate of flow and directly related to milligram per hour values. Smoking is often accompanied by higher values. The significance of these factors in defining abnormal ranges is discussed.

Salivary SCN values in hypertensive subjects coincided with those in healthy subjects.

After administration of thiocyanate salts, the amount of SCN appearing in the saliva usually is greater than in serum. There is a tendency for inverse relationship between the amount of SCN appearing in the saliva and the concentration at the time of ingestion. These findings appear relevant in judging SCN distribution in body fluid.

We are indebted to Dr W E Griesbach, Goitre Research Department, Ohio University, for helpful criticism and to Dr E P Neale, Secretary Auckland Chamber of Commerce for valuable help in analysing the statistical data.

LABORATORY METHODS

A MODIFIED METHOD OF PREPARING THE J S B STAIN

REGINALD D. MANWELL, SC D, AND PHILIP FELDSON, BS
SYRACUSE, N Y

SINCE the introduction of blood staining, which is generally credited to Ehrlich,¹ many techniques have been developed, most of them modifications of the method devised by Romanowsky and published by him in 1891.² Of these the most widely adopted have been the methods of Leishman,³ to Wright,¹¹ and Giemsa.⁴ More recently the method recommended by Field for staining thick films has been accepted widely. But a completely satisfactory stain for the demonstration of blood elements and blood parasites has yet to be discovered, as evidenced by the continual appearance of new processes. Some stains are expensive others may be cheap but do not keep well in all climates or they may be difficult to obtain. Still others, such as Giemsa's, stain too slowly.

For these reasons the appearance of the J S B stain (Singh and Bhattacharya)¹⁰ was welcomed by many laboratory workers. Its advantages have already been set forth by its originators and by one of us (R D M).⁷ When properly prepared and used, it stains very quickly, giving excellent differentiation of the commonly encountered blood protozoa, it keeps well in aqueous solution for months and costs very little to make. The ingredients chiefly methylene blue and eosin, are available almost everywhere. It is a Romanowsky stain, in many respects similar to Field's.⁸

However, the method of preparation originally recommended has proved unreliable, and the work herein reported was initiated in an attempt to improve it.

The J S B staining process requires two solutions, one of which (Solution 1) is prepared by an acid oxidation of methylene blue and the other by making a 0.2 per cent solution of water soluble eosin in tap water. It is the preparation of Solution 1 which has proved troublesome. The directions originally prescribed for making the two solutions are as follows:

Solution I is made up from the following ingredients

Medicinal methylene blue	0.5 gm
Potassium dichromate	0.5 gm
Sulfuric acid (1 per cent)	3.0 c.c.
Water	500.0 c.c.

From the Department of Zoology, Syracuse University.
Aided by a grant in aid from the National Institute of Health, Bethesda, Md.
Received for publication, Aug. 7, 1947.

Dissolve the methylene blue thoroughly in 500 cc of water. Add the 1 per cent sulfuric acid, mix thoroughly, and then add the chrome salt. A heavy amorphous purple colored precipitate of methylene blue chromate forms. Heat in an autoclave at a temperature of 100° to 109° C and a pressure of 0 to 5 pounds for three hours. At the end of this period the solution turns blue which indicates almost complete polychroming. If the color remains greenish, further heating for another hour or so is required. If the temperature is allowed to rise above 110° C, the oxidation of methylene blue may be carried too far and the solution will turn a violent purple.

When the solution has turned deep blue after three hours' boiling, allow it to cool at room temperature. Then add 10 cc of 1 per cent potassium or sodium hydroxide solution, drop by drop, very gradually while constantly shaking the flask. After the total amount of alkali has been added, transfer half of the contents of the flask into another of the same capacity and continue shaking for fifteen minutes more. Transfer the contents of the flasks into each other. In this way the precipitate will gradually get dissolved and the solution will turn deep blue with a violet iridescence. Leave it at room temperature for forty-eight hours, for the solution to mature, afterward filter through a soft filter paper. The solution will improve in staining qualities with age.

Solution II. This is readily prepared by dissolving 1 gm of water soluble eosin in 500 cc of tap water. A freshly prepared eosin solution may not yield as satisfactory a stain as one which has turned deep red after some use.

After considerable experimentation we have found it best to filter out and collect the precipitate which forms after removing the mixture of methylene blue, dichromate, and acid from the boiling water bath (which we prefer to the autoclave) and cooling, and to dissolve it in 500 cc of M/20 Na_2HPO_4 . This solution should be allowed to mature for forty-eight hours, after which it is ready to use. It will keep well for some weeks, or even months, so that one may keep it on the laboratory table ready for use when needed. This fact makes the I S B stain one of the most convenient of all Romanowsky stains.

If it is desired to dry the precipitate, it should be done at room temperature. A vacuum desiccator will be found convenient. The dried stain appears to keep very well and may be redissolved as needed. A 0.1 per cent solution (100 mg to 100 cc of M/20 Na_2HPO_4) is easily made up and stains very satisfactorily.

Another method which may be used, but which we have found more cumbersome and less reliable, is to increase the amount of alkali added to neutralize the acid mixture after removal from the water bath or autoclave. Care must be used to keep the pH from passing 8.5, and the reaction becomes very sensitive when the hydrogen ion concentration reaches 7.5. A glass electrode pH meter is necessary for this purpose.

The yield of precipitate when the stain is prepared according to the formula given is about 0.56 gram. The use of several batches of methylene blue from many different manufacturers revealed no significant variations either in the amount or quality of the product, although it was at first suspected that such variation might be a possible reason for the frequent failure to obtain satisfactory results when the original directions were followed. The stain which comes out of solution in the form of very long, needle like crystals of a

deep blue color. In ethyl alcohol it has a solubility of 2.2 ± 0.05 Gm per liter, and in distilled water the figure is almost the same being 2.1 ± 0.05 Gm per liter.

Since Holmes and French found that the amount of dichromate used had a great deal to do with the character of the product several experiments were tried in which this reagent was reduced in quantity. When it was halved, it was found that the precipitate amounted to only about 0.51 Gm and when it was cut to 0.10 Gm (a reduction of 80 per cent) the yield was but 0.15 Gm (These and other data relating to these experiments are summarized in Table I). In this last instance the character of the precipitate was also altered and it appeared that a large proportion of the methylene blue remained unoxidized.

Thus it appears, although some reduction of the dichromate may be made that any considerable change in this direction will reduce the yield of stain. In this connection it is necessary to point out that the experiments of Holmes and French are not wholly comparable to those we are reporting, since they used much more concentrated solutions of acid and methylene blue and a much shorter cooking time.

TABLE I EFFECT OF REDUCTION IN AMOUNT OF DICHROMATE ON YIELD AND COMPOSITION OF STAIN

K ₂ CrO ₇ (GM)	H ₂ SO ₄ 1% (ML)	METHYLENE BLUE (GM)	YIELD (GM)	EO40 EO70	STAIN		ABSORPTION MAXIMA (IN DISTILLED WATER) (Mμ)
					AZURE B (%)	METHYLENE BLUE (%)	
0.50	3.0	0.50	0.569	1.36	74.7	25.3	654 662
0.25	3.0	0.50	0.516	0.90	32.4	67.6	660 664
0.10	3.0	0.50	0.150	0.82	22.4	77.6	660 665

E is the extinction coefficient at the two wave lengths mentioned. The ratio change with changes in the proportion of methylene blue. See Holmes' for details of method and standard curve. The test were done with samples of stain in 50 per cent ethyl alcohol.

To get some information about the composition of the stain the precipitate was tested with the spectrophotometer, using samples dissolved in distilled water. The results indicated that it was a mixture of methylene blue and azure B in each case, the percentage of the latter being greatest (about 75 per cent) when the full amount of dichromate was used. These figures are also summarized in Table I.

Fig. 1 shows the absorption curve is determined with the spectrophotometer for the stain in aqueous solution when prepared with the amounts of ingredients specified in the original formula.

As a result of these determinations, it seemed worth while to try making up Solution I from methylene blue and commercial azure B using a mixture of approximately one part of the former to three of the latter and an amount of water sufficient to give a dye concentration equivalent to the laboratory prepared JSB stain. This solution was found to stain well although it did not seem quite equal to the latter. It also was found that the exact proportions of the two dyes were not very important; variations of perhaps 10 per cent either way did not change the quality of staining very much.

Fig 1—Absorption curve of JSB stain in H₂O

In this regard it is worth pointing out that our results disagree with those of Holmes and French⁵ who believed that azure B had little staining value, but they are in accord with those of Roe Lillie and Wilcox.⁶ However, Holmes and French used a different technique.

In using J S B as a blood stain we have found it an advantage to buffer the wash water so that its initial pH (6.2 to 6.6) will be retained. For this purpose we use $\text{Na HPO}_4 \cdot 7\text{H}_2\text{O}$ and KH_2PO_4 in the proportions of 0.417 and 0.752 Gm., respectively, dissolved in two liters of distilled water.

Our experience indicates that this stain has very definite advantages over any of the other Romanowsky stains in common use. At current prices the materials for making it cost about one sixth as much as Giemsa powder and the disparity is considerably greater if Giemsa is purchased in stock solution. It also lasts much longer after being made up. It is as rapid as any stain other than Fields' and is good for both thick and thin smears. Differentiation of the common protozoan blood parasites is excellent. We have had no opportunity to try it on blood spirochetes but it may prove useful for these also.

As a blood stain, it may be less satisfactory for routine use than Wright's and Giemsa's because small variations in the staining time may cause some differences in the appearance of the various blood elements. However, if these factors are controlled carefully, it should be of value for these purposes also.

In this laboratory it has proved useful for the staining of vaginal smears (from rats) and has saved time as well as given good cell differentiation.

Correspondence* indicates that with a slight modification the J S B stain is very useful in the staining of dried films of milk and cream. However, the stain as modified in this way does not give satisfactory staining of blood parasites. (The chief change was the employment of a much lower pH 5.0 to 5.5 for Solution I. The smears themselves required fixing in a chloroform alcohol reagent for several minutes in order to remove the fat. After staining examination under the microscope was done with a suitable color filter to increase the contrast.)

SUMMARY

Several modifications of the original method of preparing the J S B stain are described. They involve filtering out the precipitate resulting from the oxidation of methylene blue and redissolving in M/20 Na HPO_4 which serves both as a solvent and a buffer. The precipitate also can be dried and kept more or less indefinitely without deterioration.

Spectrophotometric tests show that the active staining agent is a mixture of azure B and methylene blue in a proportion of about 3 to 1. A solution of commercial azure B and medicinal methylene blue in these proportions was found to be a good substitute for the laboratory prepared product although apparently not quite equal to it.

CRYSTALLINE HEMIN SOLUTIONS AS PERMANENT STANDARDS FOR HEMOGLOBIN ESTIMATION

B L HORECKER, PH D
BETHESDA MD

IN A previous communication¹ solutions of crystalline hemin at pH 9.4 were proposed as standards for the colorimetric determination of hemoglobin. Such solutions can be reproducibly prepared from weighed quantities of crystalline hemin, and they have absorption spectra closely paralleling those of alkaline hematin from whole blood. With the proper filters and conversion factor the colorimetric determination of hemoglobin is thus referred to a readily available gravimetric standard. It was hoped that the standardization could be further simplified by the use of permanent standards kept in sealed colorimeter tubes and studies were begun to determine the long time stability of such solutions. They were found to have a useful life of about nine months, following which a progressive decrease in intensity became apparent.

Similar results have recently been reported by King² who investigated the stability of hemin solutions at pH 9.4 and found a sharp drop in intensity after nine months. The standard solutions used in the present study were prepared in sealed colorimeter tubes and autoclaved to prevent the growth of microorganisms. Such treatment does not affect the stability, since the results obtained are in agreement with those obtained by King.

Since these solutions have only a limited stability the more reproducible standards previously reported are considered more convenient and reliable. It should be noted that the hemoglobin/hemin intensity factor to be used is determined by the nature of the filter,² and a given factor may not be carried from one filter to another.

A TIDAL VOLUME RECORDER FOR ANESTHETIZED DOGS

HAROLD M. PECK, M.D., AND WILLIAM S. WALLER, B.S.
GLENOLDEN, PA.

A PRACTICAL recorder for quantitatively and continuously measuring tidal volume must fulfill several requirements. It should (1) record the tidal volume for long periods of time without demanding the attention of the investigator, (2) record accurately, during rapid and marked changes in respiratory rate, the tidal volume and duration of inspiration or expiration, and (3) leave a permanent record that easily can be converted to volume. The recorder should not require a large area for the record or present marked resistance to the flow of air.

The usual methods of recording respiration, such as lateral tracheal pressure, the chest pneumograph, or the Gaddum method,¹ measure the respiratory rate and, at best, relative changes in tidal volume. However, these changes are magnified or minimized by the speed of inspiration or expiration. The recorder that most nearly satisfies the requirements was that described by Wright.² Use of this recorder was limited by the space required by the apparatus.

We found that the apparatus described below fulfilled the listed requirements. Tidal volumes of anesthetized dogs have been measured for several hours without adjusting this apparatus. Respiratory rates of 2 to 60 per minute and tidal volumes of 25 to 400 cc have been recorded satisfactorily. Slow or rapid inspirations did not affect the operation of the apparatus. The maximal height of the record was about 4 cm (equivalent to 400 cc) and the base line was horizontal. The resistance of the instrument to the flow of air varied between 5 and 20 ml of water. The apparatus was mounted under the dog table.

APPARATUS

Fig. 1 is a schematic diagram of the apparatus. Fig. 2 is a diagram of the double piston valve, drawn to scale. The numbers in the following description refer to Fig. 1 unless otherwise indicated. (1) A metal to metal contact switch operated mechanically by contact with the top of the spirometer. It is inserted into the circuit between one side of the secondary coil of the transformer and one side of the relay coil. (2) A mercury contact switch constructed as a first class lever. Electric connections are made through the mercury cup (b) and the fulcrum (f). One connection is to the transformer and the other to the relay coil. This switch activates the relay. A brief contact is sufficient because one pan of the relay contact points (d) continues the activation of the coil until

From the Department of Pharmacology, The Medical Research Division, Sharp and Dohme Inc.

DRAW BY W.S. WALLER
CO. ED. M.M. GARRATT

the switch (1) is opened. Air exhaled from the dog forces one end (a) of the lever up to make the opposite end (b) contact the mercury in the cup. Water traps (8) on each side of a tracheal cannula direct the flow of air to and from the dog. A T-shaped tracheal cannula was made of 10 to 15 mm diameter glass tubing. A small side tube was added to measure tracheal pressure. All air passages were of large diameter. Movements of the spirometer were transferred to sooted kymograph paper by means of a cord connected to the spirometer and a vertically moving recording point.

The working sequence of the apparatus is as follows. When the dog is in respiratory rest the spirometer (7) is filled with air, and the switches (1), (2) and the relay (5) are open. The piston valve (3) is in position to connect the tracheal cannula with the spirometer and to direct the flow from the air line through the escape holes (e). (See Fig. 2, broken lines, for the position of the valve.)

As the dog inhales, the spirometer descends and the switch (1) closes to connect one end of the secondary coil of the transformer to the relay coil.

As the dog exhales, the switch (2) closes and completes the circuit between the opposite ends of the secondary coil and the relay coil. This activates the coil and closes the contact points. One pair of the contact points (d) continues the activation of the relay coil regardless of the position of the switch (2). The other pair of points (c) activates the solenoid (6) which pulls the double piston valve (3) to the position illustrated by the solid lines in Fig. 2. This shift in position blocks the connection between the tracheal cannula and the spirometer and directs the flow from the air line to the spirometer through the perforated piston valve. As the spirometer is filled, the switch (1) opens and breaks the connection between the transformer and the relay. This returns the apparatus to the original position ready for another respiratory cycle. Filling the spirometer requires less than a second.

DISCUSSION

The tidal volume recorder has been used in our laboratory as a part of routine acute experiments. The records were easily read and gave information not obtainable by simultaneous lateral tracheal pressure or by chest pneumograph methods. Epinephrine administration resulted in either a temporary decrease or an increase in tidal volume, depending on the degree of blood pressure change, followed by tidal volumes that usually were greater than the control tidal volumes. Histamine usually caused a decrease in tidal volume lasting longer than the blood pressure drop. Sodium pentobarbital and sodium barbital caused a decrease in tidal volume.

Tidal volume is influenced by simultaneous changes in pleural pressure, bronchodilatation or bronchoconstriction, duration of inspiration, and the status of the pulmonary capillary bed. Pleural pressure was shown to vary when bronchodilator or bronchoconstrictor compounds were administered.^{3,4} Pleural pressure correlated with tidal volume appears to give considerable additional information even if the capillary bed status and duration of inspiration are

Fig 3—Effect of epinephrine and histamine on tidal volume (TV) pleural pressure (PP) and blood pressure (BP). Epinephrine 20γ injected intravenously at C and I. Histamine 110γ injected intravenously at F. See Table I for interpretation of the tracing.

noied, provided the latter changes are not too great. To obtain pleural pressure a balloon was inserted into the potential pleural cavity and attached to a small recording mercury manometer. The resulting records gave information that seems to indicate degrees of bronchodilatation or bronchoconstriction. Fig 3 and Table I demonstrate the results obtained when epinephrine and histamine were administered. Degrees of bronchodilatation and constriction have been indicated by dividing the tidal volume (TV) by the length of the line measuring the pleural pressure (PP) and are calculated at the points indicated on the tracing. A decrease in the tidal volume/pleural pressure ratio indicates bronchoconstriction, and an increase indicates bronchodilatation. Correlation of tidal volume and pleural pressure is being studied more completely in our laboratories.

SUMMARY

Apparatus suitable for continual, quantitative measurements of tidal volumes of anesthetized dogs is described.

A method that appears to indicate degrees of bronchodilatation or bronchoconstriction by simultaneous measurement of tidal volume and pleural pressure is presented.

RESULTS OF VACCINATION AGAINST INFLUENZA DURING THE EPIDEMIC OF 1947

CLAYTON G. FOOSLI, M.D., PH.D., JAMES SCHONBERG, M.D. AND
GWENDOLYN BARNITT, M.S.
CHICAGO, ILL.

INTRODUCTION

THE influenza epidemics of 1943 and 1945 respectively provided the opportunity for several groups of investigators¹⁻⁵ to evaluate the use of combined influenza A and B virus vaccine as a means of protection against this disease. These studies yielded highly significant results in favor of the prophylactic value of vaccination even when the vaccine was given as long as a year preceding an outbreak.⁵ Although these investigations established without doubt the importance of vaccination as a control procedure during the 1943 and 1945 epidemics, further evaluation during subsequent outbreaks in civilian groups seemed warranted. Studies on the periodicity of epidemic influenza indicated that sometime during the fall and winter of 1946-1947 an outbreak would occur. In the fall of 1946 therefore, a study was organized at the University of Chicago to test further the usefulness of vaccination for protection against influenza.

METHODS

Population—Two thousand and twenty students (men and women) living in twelve University houses were employed in the epidemiologic study. Seven hundred ninety volunteers were vaccinated and 1,230 served as controls. The vaccination program was carried out in the dormitories over a period from Nov. 6 to Dec. 6, 1946. Not more than 50 per cent of the population in a given house was vaccinated. A record was kept of each student in the test and control groups in the Student Health Clinic and all respiratory illnesses were recorded. The epidemiologic data were derived from patients reporting to the clinic for care. In order to obtain crude data on the over-all incidence of influenza, a questionnaire was sent to all the students in the test and control groups on April 6 inquiring whether they had had an illness with symptoms resembling influenza during the previous six weeks which included the epidemic period.

In addition to those in the dormitories several hundred students living in private homes, fraternity houses, and so forth, were also vaccinated in the

This investigation was supported (in part) by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, United States Public Health Service.

Presented in part before the Twentieth Annual Meeting of the Central Society for Clinical Research, October 30, 1947.

Received for publication April 1948

clinic These, along with several hundred unvaccinated students not included in the epidemiologic group, were cared for in the clinic or hospital during the epidemic period Sera from both acute and convalescent phases also were obtained from many in these groups for serologic diagnosis of influenza

Vaccines—Three different commercially prepared inactivated virus vaccines* having an A component of 25 per cent PR-8 and 25 per cent Weiss strains and a B component of 50 per cent Lee strain were employed The number receiving each brand of vaccine was approximately the same Each student in the test group was given 1 cc of vaccine subcutaneously in the deltoid region of the right or left arm Skin tests to determine sensitivity to the vaccines were not performed prior to vaccination The volunteers were questioned about sensitivity to eggs, fowl feathers, or to previous vaccinations Those giving positive histories were placed in the control group Only minor local reactions and an occasional moderately severe generalized reaction to the vaccines consisting of fever and malaise were encountered

RESULTS

Immune Response to Vaccination—The method employed for antibody determination was Salk's⁷ modification of the Hirst⁸ chicken red cell agglutination inhibition technique The immune response to vaccination (Table I) was satisfactory, as shown by a comparison of the antibody titers against the virus strains in the vaccines in sera collected before and from two to three weeks after vaccination There was no significant difference in the immune response to the three vaccine preparations

The 1947 Epidemic—Late in January, 1947, outbreaks of influenza, found to be due to influenza virus type A, were reported in Army population groups in California, Colorado, and New Jersey.⁹ Subsequently, the military personnel of other Army installations near Chicago were attacked During this period when the Army was having its main incidence of influenza, the civilian popula-

tion appeared to be relatively free from it. The peak of the epidemic among civilians occurred during the latter part of February and the early part of March.^{10, 15}

A sharp increase in the incidence of acute respiratory disease occurred among the student population at the University of Chicago during the first week of March, 1947. The majority presented symptoms characteristic of mild influenza with sudden onset, malaise, frontal headache, back pain and generalized muscle pains, and nonproductive cough. Only a few complained of sore throat.

Fig 1—Incidence of acute respiratory disease among vaccinated and unvaccinated student, reporting to the clinic for care during the epidemic period of influenza, 1947

or stuffy nose or suffered from nausea or vomiting. The epidemic was of short duration, reaching its peak March 15 and lasting a period of about four weeks (Fig 1). Before and after the period of increased incidence the weekly rate for respiratory disease was low and was essentially the same in the vaccinated and unvaccinated groups (Fig 1).

Incidence—The data shown in Table II are based on the number of students coming to the clinic and admitted to the hospital for care for acute respiratory disease. The criterion for admission to the hospital was generally a fever of 101° F or above with corresponding constitutional symptoms and cough. During the period of increased incidence of acute respiratory disease from March 2 to April 5, 1947, the attack rate was the same in the vaccinated and unvaccinated groups being 9.5 per cent. Two and five tenths per cent of the vaccinated and 2.26 per cent of the unvaccinated students were considered sufficiently ill to be admitted to the hospital (Table II). Five hundred seventy-six students from the control group and 606 from the test group returned the respiratory disease questionnaire. Forty one and eight tenths per cent of those

answering from the control group and 46.5 per cent of the test group described symptoms of upper respiratory tract infection. The great majority dated their illness during the period of increased incidence as noted from the clinic records.

TABLE II INCIDENCE OF ACUTE RESPIRATORY DISEASE DURING EPIDEMIC PERIOD FROM MARCH 2 TO APRIL 5, 1947

GROUP TREATED IN	VACCINATED (790)		UNVACCINATED (1230)	
	NUMBER OF CASES	INCIDENCE	NUMBER OF CASES	INCIDENCE
Clinic	55	7.00	88	7.14
Hospital	20	2.50	29	2.36
Total	75	9.50	117	9.50

Serologic Diagnosis of Influenza A—From Feb. 8 to April 26, 1947, acute and convalescent phase blood was collected from 192 unvaccinated individuals showing respiratory illnesses suggestive of influenza. These were tested for antibody rise to the PR-8 and Lee strains of influenza virus. No significant rise was noted against the Lee strain in any of the specimens of convalescent sera. On the other hand, as is shown in Table III, 40 per cent of the blood specimens during the first three weeks of March showed a fourfold or greater rise in titer to the PR-8 strain of influenza A virus. Only two of the twenty-nine blood specimens collected before and after the period of increased incidence of illness, however, showed significant rises in titers to PR-8.

TABLE III ANTIBODY RESPONSE TO TYPE A (PR-8 STRAIN) INFLUENZA VIRUS IN UNVACCINATED INDIVIDUALS SHOWING SYMPTOMS OF INFLUENZA IN 1947

PERIOD OF TIME	FEBRUARY 8-28	MARCH 2-8	MARCH 9-15	MARCH 16-22	MARCH		
					MARCH 23-29	APRIL 30-5	APRIL 6-26
Per cent*	16	40	41	39	28	15	13

Pairs of sera	62	400	390	410	320	134	77

*Convalescent sera showing a fourfold or greater rise in titers.

Etiological Diagnosis of Influenza—Throat washings were collected from thirty-two hospitalized patients immediately after admission by having them gargle with 10 to 20 cc of nutrient broth. The throat washings were then frozen and kept in the dry ice chest until ready for study. Two strains of influenza virus, J-16 and L-32, were isolated by direct inoculation of 0.2 cc of the unfiltered, undiluted throat washings into the allantoic cavities of 10-day-old chick embryos on the third egg passage. After the first passage, 0.1 cc of a 10^{-2} dilution of the allantoic fluid was employed. Penicillin and streptomycin (100 units per 1.0 cc of undiluted washings) were added one-half hour before the initial inoculation was made and occasionally before subsequent passages. The eggs were incubated for forty-eight hours at 99 to 100° F. All samples of throat washings were subjected to at least four egg passages before they were discarded.

Antigenic Relationship Between Influenza A Virus PR-8 and the 1947 Strains—Sixty-eight pairs of sera from unvaccinated individuals, collected be-

fore and after the infections again were tested for antibody levels against the PR 8 as well as against the recently isolated J 16 and L 32 strains (Table IV). Thirty seven of the convalescent sera showing a fourfold or greater rise in antibody titer against PR 8 also showed significant rise in titers to strains J 16 and L 32. Likewise, as shown in Table IV thirty one pairs of sera showing no significant rise in titer to PR 8 also showed no rise to the 1947 strains.

TABLE IV. INFLUENZA ANTIBODY TITERS FOR THE PR 8, J 16 AND L 32 VIRUS STRAINS IN SERA FOLLOWING VACCINATION WITH COMBINED A AND B VACCINE CONTAINING PR 8 STRAIN AND INFECTION IN UNVACCINATED INDIVIDUALS

VIRUS STRAINS	NUMBER OF PAIRS OF SERA TESTED		MEAN FOLD INCREASE
	POSTVACCINATION	CONVALESCENT	
	60	1†	
PR 8	71		5.6
J 16	1		5.2
L 32	15		5.1
			1.1
			0.7

Shown fourfold or greater increase in titer at the time of original testing for PR 8 influenza antibodies.

†Shown threefold or less rise in titers to PR 8 influenza antibodies at time of original testing.

Sixty pairs of sera collected at the time of vaccination also were retested for antibody response against PR 8 and the 1947 viruses (Table IV). Whereas the postvaccination sera showed an average increase in antibody to PR 8 of over sevenfold, no significant rise was noted to the J 16 and L 32 strains. These data show that there was no close antigenic relationship between influenza viruses causing the 1947 outbreak and the influenza A component in the vaccine. Yet the increase in antibody titers in the convalescent sera to the J 16 and L 32 and also to the PR 8 strain establishes the first two as type A influenza viruses.

Serologic Studies on Vaccinated Individuals—Acute and convalescent phase sera were obtained from 46 vaccinated individuals in the test group who came to the clinic or were hospitalized for care between March 2 and April 5. Twenty three pairs (50 per cent) showed a fourfold or greater rise to the J 16 strain of influenza virus. The majority of those showing significant rises showed less rise in antibody titer to the PR 8 strain, in all probability because of the initially high antibody level in the acute phase sera (Table V).
